Descriptive statistics for the study population at the individual level are shown in Table 3.3. Across the study area, diarrheal prevalence is 13%. While 67% of households have an improved water source, only 43% have an improved toilet. In urban areas (DHS classification), 85% of the households use an improved water source and 76% use an improved toilet. In rural areas, it is 58% and 27%, respectively. Sixty three percent of mothers have no formal education.

About 11% of the study households live in the humid lowest latitudes and 2% in the northern desert areas, with the rest in the mid-latitude savannah and steppe areas. Temperature is normally distributed with an average of 27.8□C in the month before and the month of the interview. Rainfall is positively skewed with over 58% of the children experiencing an average of less than 15 mm of rain in the 4 dekads before and of the interview. Nearly ¾ of the children live at altitudes between 25 and 500 meters, with 14% below that (nearly all coastal), and 12% at higher altitudes. Despite rapid urbanization, West Africa is still largely rural with a weighted average population density of 23 people/km^2. Only 5% of children in these surveys live in areas with population densities of 5,000 people/km^2 or more.

Variable	Value	Individuals	Percent

Variable selection

Table 3.4 shows the results of the variable selection. Asterisks (*) mark those variables with the biggest difference between global AICc and GWR AICc (Diff. AICc). As expected with these data, the GWPR model is an improvement in all cases. The only variable category with two possibilities of aggregation is rainfall, where

sum and average over the 4-dekad period give similar differences of AICc (the rule of thumb is that if the difference in AICc values between two models is less than or equal to 2, there is no real difference in the performance of the models).[14] Average rainfall was selected as it is more intuitive and comparable to average temperature.

The percent deviance explained in GWPR is a measure of local goodness-of-fit and is a type of pseudo-R^2.[34] Bandwidth is the number of sampling points included in the kernel as determined by the golden section search.

	Variable	Diff. AICc	% Deviance Explained GWPR	Bandwidth

Table 3.4: Variable selection. Diff. AICc is the difference in AICc between the global Poisson model and the GWPR model. % Deviance Explained GWPR is a pseudo-R^2 measure and bandwidth is the number of sampling points included in the kernel as determined by the golden section search.

Model building

Model building and model results are shown in Table 3.5 and Table 3.6. In Models 1-3, all terms are allowed to vary locally. Model 1 used all eight variables selected above. Because population density may have a nonlinear threshold effect where outcome changes after a critical level of density, population density and population density squared were tested in Model 2. Next, an interaction term for rainfall and temperature was tested in Model 3. Not shown are several other combinations of locally varying terms, none of which performed as well as Model 1.

In Models 4-6, the hitherto best model (Model 1) was altered such that one term was globally fixed. The three variables tested were population density, latitude, and altitude, the hypothesis being that these variables are relatively invariable across the study area and thus may influence childhood diarrhea in similar ways.

As seen in Table 3.6, the Model 1 remained the best-performing with all locally varying terms.

Model	Variables Included in Model

	Water	Toilet	Educ.	Lat.	Temp.	Rain	Alt.	Pop. Dens.	Pop. Dens. Sq.	Temp. Rain Int.
1) Eight Local	L	L	L	L	L	L	L	L

Table 3.6: Model results. Diff. Best is the difference in between the best performing model (Model 1) and the others.

Final model summary

The global Poisson regression results for Model 1 – the best performing model - are shown in Table 3.7.

When using all available data to estimate one average coefficient per explanatory variable for the entire study area, water source is not significant at the 0.10 level, toilet type is not significant at the 0.05 level, and all the other variables show high significance. A slight positive association is seen with water source, latitude, rainfall, altitude, and population density. Slight negative associations are seen with toilet type, mother's education, and temperature. The results for the GWPR for Model 1 are shown in Table 3.8 with the ranges of relative risk according to location, along with the percent of sampling points (n=4,943) which show significance (t-statistic less than -1.645 or greater than 1.645) for each covariate.

Variable	Relative Risk	P-value
Intercept	0.1496	0.0000
Unimproved water source (% households)	1.0003	0.2510
Unimproved toilet type (% households)	0.9995	0.0560
No formal education (% mothers)	0.9992	0.0120

Latitude	1.0397	0.0000
Temperature	0.9830	0.0000
Rainfall	1.0023	0.0000
Altitude	1.0001	0.0250
Population density	1.0000	0.0000

Table 3.7: Global Poisson regression results (Model 1) with relative risks and p-values.

Variable	Range of Relative Risk	% of sampling points significant
Unimproved water source *(per 10% increase)*	0.93 – 1.11	28%
Unimproved toilet type *(per 10% increase)*	0.84 – 1.10	31%
No formal education *(per 10% increase)*	0.78 – 1.14	30%
Latitude *(per 1-degree increase)*	0.02 – 15.06	48%

Rainfall *(per 10-mm increase)*	0.43 – 41.30	64%
Altitude *(per 100-m increase)*	0.33 – 2.80	32%
Population density *(per 100-pp/km2 increase)*	0.65 – 1.68	37%

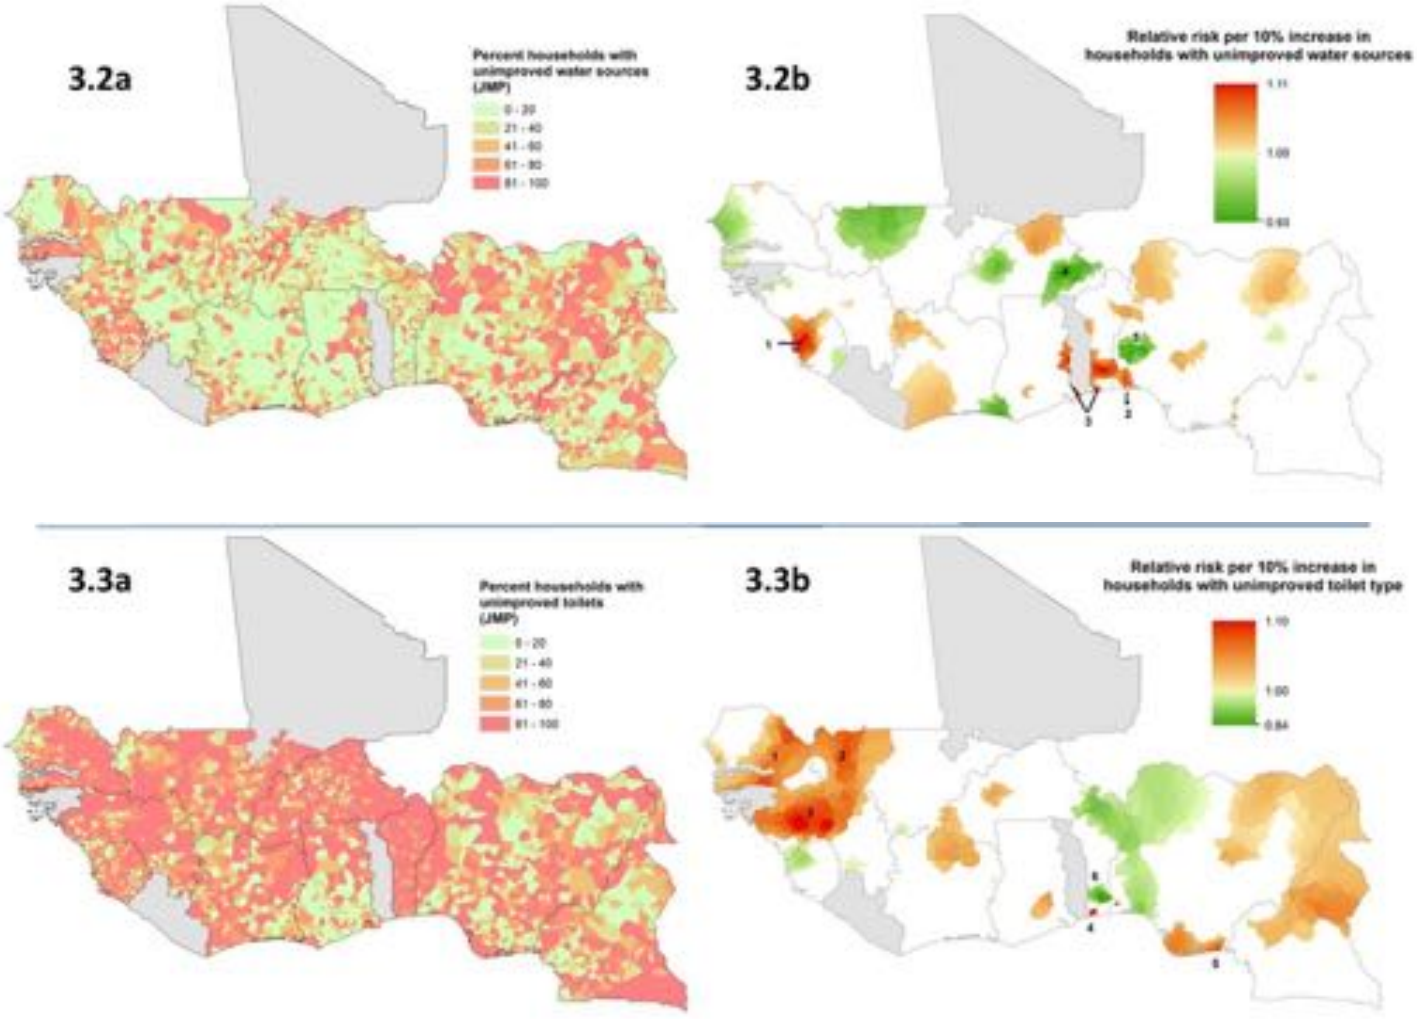

Table 3.8: Geographically Weighted Poisson regression results (Model 1) with range of relative risk and percent of significant sampling points (n = 4,943).

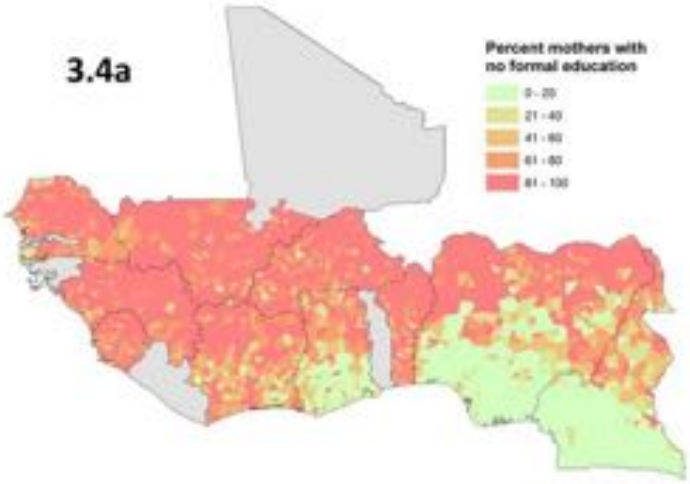
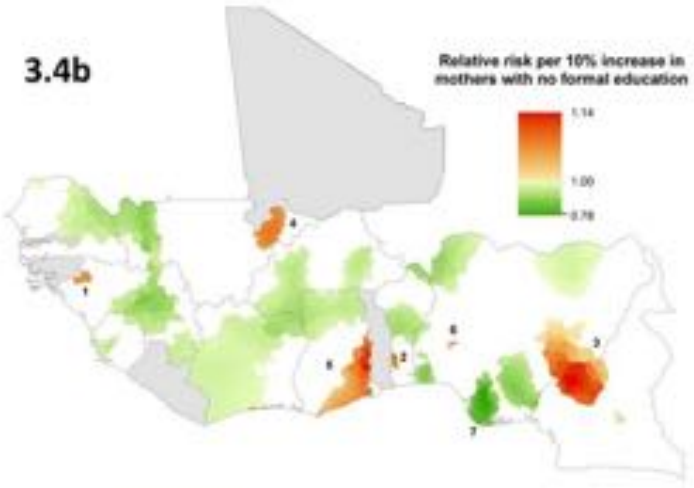


Following Fotheringham (2002), the formal test for non-stationarity is if the interquartile range (Q3-Q1) of the local regression coefficient is larger than twice the standard error of the global regression coefficient.[31] As seen in Table 3.9, all variables show non-stationarity.



Variable	Min	Max	Q1	Median	Q3	Status
Intercept	-21.308	37.931	-3.67717	-1.05873	1.48906	non-stationary

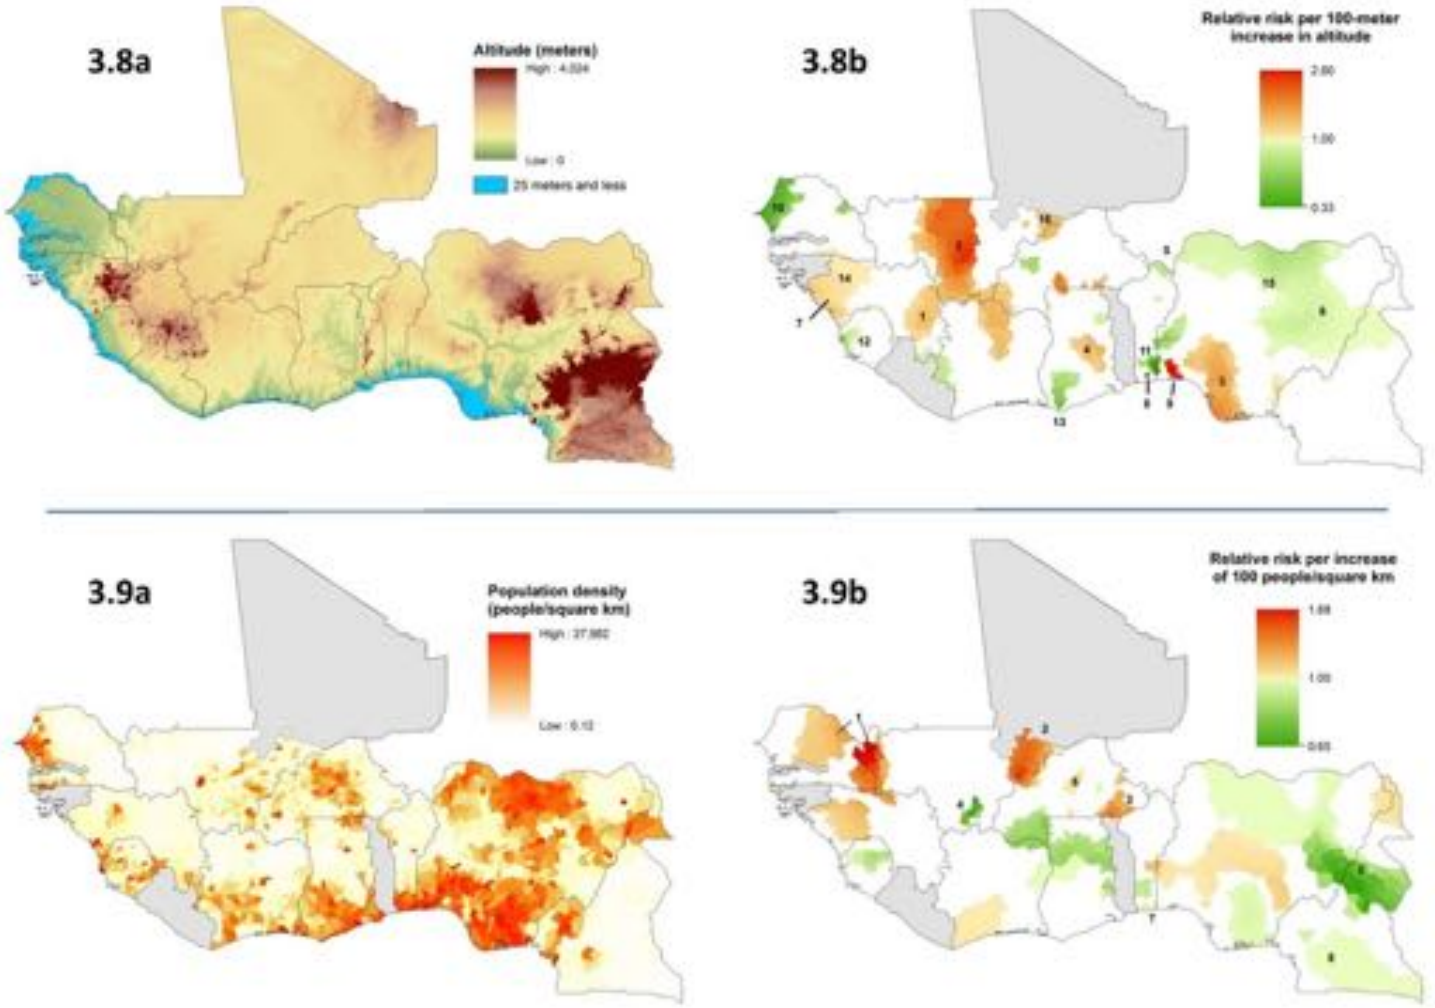

Figure 3.2 - Figure 3.9: Maps of descriptive variables (a) and GWPR coefficients (b). Numbers in (b) maps refer to the "individual variables" section, below. Gray areas were not surveyed.

Individual variables

Refer to Figures 3.2 – 3.9:

<u>Percent of households with unimproved water source</u>

Region-wide, about 33% of households have unimproved water sources. Rates of unimproved water sources are varied throughout individual countries, but in general, the proportion is higher in more sparsely populated areas.

Several major urban centers show positive associations between the percent of unimproved water sources and diarrheal disease. Coastal Sierra Leone and Guinea (1) including Freetown and Conakry have increased

risk, as does Lagos and its northern extent (2) where 44% of households have unimproved water sources. Other higher risk areas are rural mixed with more densely populated towns; for example, southern Benin and western Ghana (3). The strongest negative associations (decreased risk) are seen in eastern Burkina Faso (4) and central west Nigeria (5).

The range of relative risk for water source was 0.93 to 1.11 and the coefficient was significant in 28% of the sampling points – the lowest of all the variables.

Percent of households with unimproved toilet type

About 57% of households in the study area have unimproved toilet types. As with water source, in general, rates are varied throughout particular countries. However, the overall proportion of unimproved toilets is higher and more urban residents are without improved toilets than without improved water sources.

The strongest positive associations between the proportion of unimproved toilets and diarrheal disease are in sparsely populated central Senegal (1) and western Mali (2). Increased risk is also seen in central Guinea (3), western Benin (4), and the eastern Niger River Delta area (5) which is a mix of villages and towns. The strongest negative association is in southern Benin (6).

The range of relative risk for toilet type is similar to water source: 0.84 to 1.10 with significance in 31% of the sampling points.

Percent of mothers with no formal education

Region-wide, about 63% of mothers surveyed had no formal education. In Ghana, Nigeria, and Cameroon, there is a distinct north/south divide. In Ghana, about 15% of mothers had no formal education in the south versus

71% in north. In Nigeria, the difference is 10% versus 69%, and in Cameroon, it is 4% in the south and 63% in the north.

The proportion of mothers without formal education and diarrheal disease are positively associated in more sparsely populated areas of Guinea (1) and Benin (2) where there are high rates of no education. In Cameroon and Nigeria (3), the area of higher risk is also relatively sparsely populated, but with more of a mix between higher and lower rates of no education. A third pattern is seen in Mali (4), Ghana (5), and western Nigeria (6). In these areas of high positive association, there is a major city (Mopti, Accra, and Ilorin, respectively) with relatively low rates of no education, surrounded by rural areas with high rates of no education. Negative associations are also seen for education, most strongly in the Niger River Delta area (7).

Relative risk for mother's education ranges from 0.78 to 1.14 with significance in 30% of sampling points.

Latitude / Climate Class

In the fully humid/monsoonal climate class, higher risk of diarrhea is seen most strongly in Sierra Leone (1), but also in coastal and inland Guinea (2-3), western Côte d'Ivoire (4), and the eastern Niger River Delta (5). The northern part of Sierra Leone (6) and southern part of Cameroon (7) show negative associations, while in southeastern Côte d'Ivoire, there is no statistically significant association.

In the savannah climate class, the areas with the strongest positive associations are in southern and eastern Benin (8) and western Nigeria (9). There were both positive and negative associations throughout the northern savannah and steppe climate classes. The strongest negative associations are in southeast Ghana (10) and southern Burkina Faso (11). In the small desert section of the study area, there were no statistically significant effects.

The range of relative risk for latitude is 0.02 to 15.06 with significance in 48% of sampling points.

Temperature

The strongest positive associations between temperature and diarrheal disease are in western Mali (1) where conditions were cool and dry; eastern Ghana (2), which was cool and wet; and southern Benin (3) where it was warm and dry.

Decreased risk was strongest in central south Ghana (4) which was cool with moderate rain or warm with heavy rain; northern Sierra Leone (5) where it was warm with heavy rain or hot with moderate rain; central and southern Benin (6-7) where conditions were warm or hot and dry; and the western Niger River Delta (8) which was warm to hot with moderate to heavy rain.

Temperature was significant in 36% of the sampling points and had a relative risk range of 0.28 to 1.83.

Rainfall

The strongest positive associations between rainfall and diarrheal disease were in central Senegal (1), central Mali (2), and southwestern Benin (3) where conditions were dry with cool to hot temperatures. Negative associations are strongest in south central Benin (4), which was dry with warm to hot temperatures and northern Nigeria (5), which was dry and hot.

Rainfall showed statistical significance for 64% of the sampling points and a range of relative risk from 0.43 to 41.30. These are the highest percent significant and largest range in the study.

Altitude

Positive associations for altitude are seen in the Guinea Highlands (1), central Mali (2), and the Niger River Delta in Nigeria (3). The Lake Volta region of Ghana (4) also shows positive associations. There are negative associations in Benin and Nigeria (5) and along eastern Nigeria (6).

The low elevation coastal areas show both positive and negative associations. There are weak positive associations in coastal Guinea (7) and stronger associations in a small area of southern Benin (8) and in Lagos (9). The Niger River Delta (3) also has positive associations.

Negative associations along the coast are in western Senegal (including Dakar), eastern Benin (10-11), Sierra Leone (including Freetown), and western Ghana (12-13).

The areas of highest altitude in the region show associations in different direction; slightly positive in northern Guinea (14) and negative at the lower elevations of the Jos Plateau in Nigeria (15). Unlike these two places, which have significant populations, the highlands of Cameroon are sparsely populated and show no association between from altitude and diarrheal disease. The Bangiagara Escarpment in Mali (16) also shows increased risk.

The range of relative risk for altitude is 0.33 to 2.80 with significance in 32% of the sampling points.

Population Density

The strongest positive associations between population density and diarrheal disease are mostly in sparsely populated areas such as in eastern and central Senegal and western Mali (1), the Bangiagara Escarpment in

eastern Mali (2), and eastern Burkina Faso (3). The strongest negative associations are in sparsely populated areas in southern Mali (4) and Cameroon and Nigeria (5).

Of the largest cities in the study area, weak positive associations are found in Ouagadougou (6) and Cotonou (7) and a weak negative association in and around Yaoundé (8). Nigeria has many more large cities than the rest of the region, but there is a general pattern of weak negative associations in the north, weak positive in the slightly less populated middle belt, and negative again in parts of the south. Lagos does not demonstrate any significant associations.

Population density is significant in 37% of the sampling points with a relative risk range of 0.65 to 1.68.

Areas with multiple risk factors

Temperature and rainfall

Temperature and rainfall are both positively associated with diarrheal disease across Mali and northern Guinea, as well as in smaller areas of eastern Burkina Faso, and central Ghana and Côte d'Ivoire.

In small areas of central Senegal, central Ghana, northern Benin, and northern Nigeria, there is increased risk for rain, and decreased risk for temperature. Positive associations for temperature and negative for rain are seen in western Guinea, northern Côte d'Ivoire, and northern Burkina Faso and Nigeria.

Latitude/climate class, temperature, and rainfall

In the fully humid/monsoonal climate classes with a positive association for diarrheal disease (Sierra Leone, Guinea, Côte d'Ivoire, Niger River Delta), there was moderate to heavy rainfall with warm temperatures.

These were also the conditions in northern Sierra Leone and Cameroon where there was a negative association. In the monsoonal area of southeast Côte d'Ivoire, there is no statistically significant effect and conditions were dry or with moderate rain.

In the savannah climate class, the areas with the strongest positive associations for latitude are in southern and eastern Benin where conditions were hot and dry, and in western Nigeria, where it was hot with moderate rain.

Water source and toilet type

There are a few areas which show increased risk for diarrhea associated with both percent of households with unimproved water source and toilet type, the largest of which is in northeastern Nigeria. Others include southwest Benin and central Guinea. In western Senegal (including Dakar), northwestern Mali, central eastern Burkina Faso, northwestern Nigeria, and western Guinea there are positive associations for toilet type, but negative for water source. The opposite is the case for parts of northern Benin and Nigeria, southern Benin, and western Sierra Leone and Guinea (including Freetown and Conakry), which have positive associations for water source, but negative for toilet type.

Temperature and water source or toilet type

There are also a few small areas with positive associations for both percent of households with unimproved water source and temperature including northern Nigeria, northern Burkina Faso and northwestern Côte d'Ivoire, which were all experiencing warm-to-hot temperatures. In east central Ghana, temperatures were cool.

Areas with positive associations for diarrheal disease and both unimproved toilet type and temperature include eastern Senegal, western Mali, northern Guinea, western Guinea, western Burkina Faso, and north central Nigeria, which run from cool to hot temperatures.

Rainfall and water source or toilet type

There are several small areas with increased risk for diarrhea associated with percent of households with unimproved water source and rainfall, including northeast Nigeria, northern Burkina Faso, and coastal Benin (all dry), and two places in Ghana, both with heavy rain conditions.

Areas of positive associations between diarrheal disease and both unimproved toilet type and rainfall include western Senegal (including Dakar), central Senegal, western Mali, southwestern Benin, and the northern area of Nigeria and Cameroon which were all under dry conditions. In central Guinea, there was heavy rain.

Population density and water source or toilet type or education

There is some overlap between areas of positive associations between diarrheal disease and both population density and percent of households with unimproved water source (southwestern Côte d'Ivoire), but more so with population density and percent of households with unimproved toilet type. Areas where both these variables have positive associations are mostly in sparsely populated places such as central Senegal, western Mali, and the northern tip of Nigeria and Cameroon. A few mid-size cities also show overlap including Labé in western Guinea (which is surrounded by low population density) and Ouidah in coastal Benin.

Population density and education are both positively associated with diarrhea in sparsely populated areas of Guinea and Ghana (not including Accra) and in and south of Mopti (Mali) and Ilorin (Nigeria). Areas of positive

associations for education and negative for population density include eastern Ghana, western Benin, and parts of western Nigeria.

Altitude and water source or toilet type

There are areas of positive associations between diarrheal disease and both altitude and percent of households with unimproved water source in Guinea (including Conakry), and Lagos and its northern environs. Altitude is negatively associated and percent of households with unimproved water source is positively associated in Sierra Leone (including Freetown), northern Nigeria, and smaller areas in Ghana (Obuasi town) and Benin (including Bohicon town).

Positive associations for unimproved toilet type and altitude overlap in two low elevation coastal areas – the north coast of Guinea, and the Niger River Delta area in Nigeria as well as in relatively low areas such as along the Niger River in Mali and the Lake Volta area in Ghana. There is also overlap in the highlands of northern Côte d'Ivoire/southern Burkina Faso. Areas where altitude is negatively associated with diarrheal disease and toilet type is positively associated include western Senegal including Dakar and parts of northern Nigeria and Cameroon.

3.4 Discussion

While causality cannot be inferred from this cross-sectional study, the analysis has shown that there is spatial variation in the relationship between childhood diarrhea and key socio-economic, climatic, and environmental characteristics in West Africa.

The global Poisson model gives one coefficient per explanatory covariable for the whole study area. Thus, the interpretation would be that a one-unit increase in the covariables latitude, altitude, rainfall, and population density slightly increased relative risk of diarrheal disease, while a one-unit increase in the covariables temperature, percent with unimproved toilet type and percent of mothers with no formal education slightly decreased relative risk at the 0.10 level, *ceteris paribus*. Percent with unimproved water source shows no statistically significant association with diarrheal risk from a global model perspective. Overall drier climates (in West Africa, higher latitudes) are often associated with elevated diarrhea risk due to threats to food security, and it is plausible this is the case for higher altitudes as well.[5,6] However, averaged over the whole study area, rainfall increases risk, perhaps due to the contamination of water sources. Increasing risk with increasing population density implies that there is an urban disadvantage in this area for child health, perhaps due to failed infrastructure and lack of access to services for poorer households. Decreased temperatures may be overall protective in this study region because of decreased evaporation of water sources, which can concentrate pathogens, and decreased fly activity. The results for percent with unimproved toilet types is unexpected, but may speak to findings from other studies which show that increased coverage of improved latrines is not necessarily protective if communities still have high rates of open defecation or low rates of handwashing with soap.[40] Regarding the similar result with the educational attainment of mothers, perhaps education is more important at the household level than the community level. For example, a study of 28 subSaharan African countries found no statistically significant decreased odds of child mortality in communities (defined as DHS sampling points) where there was a relatively high proportion of mothers with secondary or higher education.[41] Overall, these small coefficient values may indicate that there is spatial variation which is averaged out in the global model.

The GWPR analysis shows that the relationships between these covariables and diarrhea are more complex, with each covariable acting as both a risk factor and apparently, as a protective factor, depending on location.

Additionally, there are specific locations for each variable where it is statistically significant and places where it is not.

The range of risk for different variables is considerable (Table 3.8). The household-level variables of percent of households with unimproved water source and toilet type and percent of mothers with no formal education have the narrowest ranges and are fairly centered around a relative risk of 1.0. Decreased risk associated with these variables is difficult to interpret, but perhaps there are other factors which drive the disease pathway more strongly. For example, in the lower Niger River Delta area, it seems that having a higher proportion of mothers without education is protective against diarrheal disease. However, this area also has increased risk due to poor sanitation, which could be the factor that drives diarrheal incidence more strongly.

Water source, sanitation, and education are modifiable risk factors and their improvement is often the aim of development projects and global initiatives such as the Sustainable Development Goals.[42] There is evidence that integrated approaches such as joint education and sanitation programs increase the impact of health programs and are more cost effective than singular approaches.[43] Additionally, risk factors for many conditions affecting children such as diarrhea, malnutrition and pneumonia are similar.[1,44] Therefore, while many different approaches are necessary to improve child health and none should be devalued, the type of analysis shown here could indicate which risk factors are more prominent in particular locations and could assist with strategic planning, resource allocation, and coordination. For example, in northeastern Nigeria, diarrhea risk is affected by both water source and toilet type, so increased services in both water and sanitation may be important to decrease diarrheal disease. In other places, however, one intervention may take precedence over another such as water source improvement in Conakry and Freetown and sanitation improvement in Dakar.

Risk associated with population density has a slightly broader range, from 0.65 to 1.68. Explicitly, this means that an increase of 100 people per square kilometer invokes as much as a 35% decreased risk for diarrhea in some places, but the same stimulus invokes up to a 68% increase in risk in other places. The interpretation is that there is an urban advantage for diarrheal disease in places such as Yaoundé, but an urban disadvantage in Ouagadougou and Cotonou. In Cameroon, which has large sparsely populated areas due to mountains and rainforest, the concentration of people may improve child health by promoting economic opportunities, adequate health care, infrastructure and housing. However, in other urban settings, the poor live in slums with sub-standard infrastructure and housing and may not be able to take advantage of health services, all of which increases risk of childhood diarrhea.[45]

Because of urban health advantage and disadvantage, increasing population density and urbanization in the developing world is a major area of both concern and opportunity.[46] In the ten countries studied here, population density is comparatively low with a median of 65 people/square km in 2010 (the same as present day Mexico).[47] However, by 2050, density is expected to increase 2- to 3-fold such that Nigeria will have the same population density as present day India.[47] Additionally, the populations in seven of the ten countries in this study were majority rural in 2010, but by 2050, all will be majority urban from 52% in Burkina Faso to over 70% in Côte d'Ivoire.[48] This means that while sparsely populated rural areas are and will continue to be important in the fight against diarrhea and other diseases, urban health will impact a growing proportion of the population. In West Africa, the places likely to remain relatively rural are the northern Sahel (the southern edge of the Sahara Desert) and mountainous regions such as in Cameroon. Urban growth is likely along developing international highway systems such as the coastal roads from Lagos to Nouakchott (Mauritania), across the Sahel from Dakar to Ndjamena (Chad), and along the Ibadan-Lagos-Accra corridor, which has a current population of about 25 million people.[49,50] This analysis indicates that responses to increased or

decreased population density will differ by location, so that one strategy may not be appropriate for planning for future populations. For example, coastal cities may face specific risks from climate-sensitive diseases because crowding and poor infrastructure could be exacerbated by storms, flooding, and rising sea levels.[51,52]

Climatic and environmental factors have the largest ranges of relative risk, especially rainfall where an increase of 10 mm invokes up to a 57% decrease in diarrhea risk, but also up to a 41-fold increase, depending on location. Temperature and rainfall data can be difficult to interpret because of the nature of survey fieldwork. Interviews within each sampling point were conducted within a maximum of 4 days; thus the temperature and rainfall data are accurate. However, within sub-national regions, interviews may be spread out over months, thus creating a "patchwork" of different temperature and rainfall regimes. This could lead to bias both in the analysis of data and in the interpretation. For example, interviews were conducted within a short time span in western Mali and northeast Nigeria and provide a snapshot of climatic conditions. In places like Burkina Faso, however, relationships between climate and diarrhea may be hidden within the multiple temperature/rainfall regimes. Here, a few areas with more stable measures are discussed. Compared to the rest of the study area, children in western Mali and eastern and western Guinea, who were experiencing cool temperatures, were at increased risk of diarrhea. Children in northeast Nigeria, where it was hot, had decreased risk. In western Mali and northeast Nigeria, conditions were dry and are associated with increased risk. In eastern and western Guinea, very rainy conditions decreased risk. Therefore, a preliminary interpretation may be that warmer temperatures or heavier rainfall are protective for diarrhea in some areas. However, much depends on seasonality and climate type, which is not fully captured here. Risk is decreased in higher latitude steppe areas in western Mali and northeast Nigeria, both of which were in the dry season. However, risk increased in eastern Guinea, which was in the savannah rainy season. Increased risk is seen in coastal Sierra Leone and Guinea, where rainfall and temperatures were quite high in a monsoonal climate

class, indicating there could have been a high presence of bacterial pathogens and perhaps contamination of drinking water sources.[53] Conversely, higher risk in western Mali where it was cool and dry in a steppe climate class could indicate the presence of viral pathogens such as rotavirus, which prefer cooler temperatures.[53]

Altitude also had a broad range of relative risk, from up to a 67% decrease in risk per increase of 100 meters in elevation up to a nearly 3-fold increase of risk. In low areas, including along the coast, risk may decrease with higher elevations since this would reduce exposure from flooded sanitation systems during storms or flooding (which is not captured in this analysis). Decreased risk is seen in low-lying parts of Senegal (including Dakar), Sierra Leone (including Freetown), and western Ghana, but the opposite is found in coastal Guinea and Benin, central Mali, Lake Volta, Lagos and the Niger River Delta area. This implies that compared to the rest of the study area, low elevations are protective in these areas at the time of the survey, perhaps because livelihood opportunities (e.g., natural crop irrigation and fishing in Lake Volta and along the Niger River) generally benefit child nutrition and health and outweighed risk from flooding. Higher elevations may be protective in the Guinea Highlands and the Bangiagara Escarpment in Mali compared to other areas, perhaps because these populations are quite sparse and isolated, which can thwart the spread of infectious disease.

Despite multiple challenges, communities in Africa have shown resilience and adaptive capacity for building on strong social networks, diversifying crops and livelihoods, migrating, and exploiting natural resources.[54] New threats and opportunities from climate change will require new adaptation measures to protect child health. Surface temperatures have increased over West Africa and the Sahel for the past 50 years and are projected to rise between 3 and 6□C above late 20th century baseline by the end of the 21st century.[54] There is more inter-model variation in rainfall projections in West Africa than for temperature, both in amplitude and direction of change. Some models project that there will be more extreme rainfall days in May and July across West Africa and the Sahel and more intense and frequent rainfall in the Guinea Highlands and Cameroon

mountains.[54] Sea-level rise is also a threat to some areas of West Africa, especially Nigeria where some 3 million people may be flooded per year by 2100.[52]

The type of analysis shown in this paper here could help improve adaptation measures. For example, the risk of diarrheal disease in parts of Mali and Guinea may be especially sensitive to temperature changes and also have increased risk associated with sanitation and so therefore could be targeted for adaptation interventions. Similarly, coastal Benin, which is subject to sea level rise, shows sensitivity for diarrheal disease to rainfall as well water source and toilet type and could be an area of particular concern.

3.5 Conclusion

In this research, the associations between childhood diarrhea and key socio-economic, climatic, and environmental characteristics were first studied in a global model and then in terms of their spatial stationarity across West Africa. The global model produced coefficient values which only partially support the original hypotheses. Water source type – generally considered a key indicator in the study of diarrheal disease - was not statistically significant. Latitude, altitude, and population density coefficients were in the expected direction with increases resulting in increased risk. Rainfall and temperature coefficients were in the opposite direction as was hypothesized with increased rainfall and decreased temperatures increasing risk. Increases in the percent of households with unimproved toilet type and percent of mothers with no formal education apparently decrease risk. However, the coefficient values were all close to 1 and are interpreted as averages which mask both positive and negative associations at different locations. For a covariable such as rainfall, for example, there is evidence that both too little and too much precipitation could be detrimental to child health depending on where a particular child lives.

In the Geographically Weighted Poisson Regression model, every covariable was found to be non-stationary.

This partially supports the original hypothesis which posited that some associations would be stationary (climate class/latitude, altitude, and population density), others would be non-stationary on a regional scale (rainfall, temperature), and the remainder (water source, toilet type, and mother's education) would show stationarity at the country level and non-stationarity at the regional level. This shows that associations between diarrheal disease and a variety of factors differ over space, speaking to the importance of spatial methods and analyses at different spatial scales. In the GWPR model, every covariable also showed positive and negative associations (increased or decreased risk) depending on location. This supports the original hypothesis for the environmental and climatic covariates as there is evidence for both protective and detrimental outcomes resulting from urban living, high or low rainfall, overall arid or monsoon climates, etc. Consistent positive associations were expected for the socio-economic factors (increased percentage of households with unimproved water sources and toilet types and percent of mothers with no formal education would be associated with higher risk), and it is difficult to interpret the dynamics where there are negative associations.

Water source, toilet type, education, population density, temperature, and altitude had as much as a 72% decrease in risk (for temperature), up to a 2.8-fold increase in risk (for altitude), and with an average of 32% of sampling points statistically significant at the 0.10 level. Latitude and rainfall had wider ranges and a greater percentage of statistical significance. Latitude invoked as much as a 98% decrease in risk and up to a 15-fold increase with 48% of sampling points significant, and rainfall invoked up to a 57% decrease in risk and as much as a 41-fold increase with 64% of sampling points significant.

Thus, the GWPR analysis as a whole shows complex patterns of risk for diarrheal disease which were masked by the global model.

This analysis is best seen as an exploration of regional dynamics which, with further research, could be useful in discerning areas where development and adaptation initiatives including specific interventions could reduce diarrheal disease and improve child health overall. In many areas, risks associated with different covariables were overlapping, indicating that integrated interventions are key. Areas of special interest include urban centers, low-elevation areas (coastal and along rivers), remote areas such as western Mali which face multiple risk factors, conflict zones (northeast Nigeria), and special populations such as the Dogon who live along the Bangiagara Escarpment.

The main strength of this study is that it uses the relatively new method of Geographically Weighted Poisson regression to examine spatial variation in associations between risk factors and a major cause of child morbidity and mortality in a high-burden area. It contributes to other GWR studies on disease and risk factors, most of which show that a global statistical models may produce misleading results.[15] The study also contributes to the small body of literature on GWPR by including eight socio-economic and environmental/climatic variables whereas most studies use fewer variables of one type. It is the only health study to our knowledge that uses latitude as a proxy for climate class, and one of few that examines altitude and diarrheal disease empirically. Finally, this study introduces several techniques not seen in other GWPR studies. One is the selection of variables for modeling using AICc to determine which aggregation of data will contribute most to model performance. Second is showing the percentage of sampling areas points with statistical significance for each coefficient so that researchers have a numeric sense of significance in addition to the visual aid of maps. Thirdly, this paper improves upon mapping techniques hereto employed by making both the magnitude and direction of the associations explicit.

The study has several limitations, most notably that it is an ecological study and cannot be used to make inferences at the individual level. Also, the survey data used here introduces temporal complexities at

different levels. First, there is a five-year difference between the earliest and latest surveys, during which time considerable progress (or deterioration) can occur, making a trans-national comparisons difficult. Secondly, in places where the survey fieldwork was spread out over weeks or months, variables which can change quickly such as rainfall were inconsistent and difficult to analyze and interpret. Thirdly, the 2-week recall period for diarrhea introduces bias. Finally, there are several weaknesses with GWR itself, including multicollinearity across local estimates.[55] The method is best used as an exploratory method and not to definitively confirm spatial non-stationarity.[32]

Future research on this topic could take several approaches. One would be to focus on smaller spatial and temporal scales which should provide more consistency and greater detail, perhaps with less evidence of nonstationarity.

Chapter 4. Conflict and Health: Has the Boko Haram Insurgency in Northeast Nigeria Affected Childhood Malnutrition and Diarrheal Disease?

Abstract

This research examines the relationship between conflict and childhood malnutrition and diarrheal disease in Northeast Nigeria whose residents have been subjected to fighting between the Nigerian government and Boko Haram - an extremist Islamist movement - since 2009. Using two household surveys from before and after the Boko Haram insurgency started, a double-difference (difference-in-difference) approach was used to assess the impact of the conflict on weight-for-height, height-for-age, and weight-for-age z-scores; moderate/severe wasting, underweight, and stunting; and diarrhea prevalence. Results suggest that if children exposed to the conflict had not been exposed, their average weight-for-height z-scores would be 0.49 standard deviations higher ($p < 0.001$) than they are, bringing the average from -0.74 to -0.25 (as per the World Health Organization, from a "serious" nutritional crisis to a "poor" one). Additionally, the prevalence of moderate/severe wasting would be 13 percentage points lower (mean z-statistic -4.2) than it is, bringing the proportion down from 23% (a "critical" nutritional crisis) to 10% (a "serious" nutritional crisis, and close to the average for all of West Africa, which is 9%). Diarrhea prevalence also improves in the counterfactual scenario with a decrease of 8 percentage points (mean z-statistic -3.3), bringing rates down from 20%, to 12% (close to the overall Nigerian average of 10%). The double-difference estimate was not statistically significant for weight-for-age z-scores or moderate/severe underweight and height-for-age and moderate/severe stunting did not meet the common trends assumption. Descriptive evidence suggests that poor child health outcomes in the conflict areas of Northeast Nigeria may be due to disruptions to infrastructure and social services and increased food insecurity in an already resource poor area. Although causal inference is somewhat limited since other unidentified factors may contribute to both conflict and malnutrition/diarrhea, the findings merit further research because of their potential importance to children living in extreme circumstances.

4.1 Introduction

Children under five years old in developing countries are particularly vulnerable to health risks because their immune systems are not yet fully effective, they are dependent on others for care, and they are exposed to hazards such as unclean water and food insecurity.[1] In 2015, 5.9 million children were expected to die with 80% of those deaths in sub-Saharan Africa and South Asia.[2] A child in a conflict setting is twice as likely to die as a child in a stable environment.[2,3]

Conflict affects child health through multiple pathways both directly and indirectly. Community and household resources may be diminished as funds are diverted away from social services (such as immunization programs), prices for food and other commodities rise, and fear or physical obstacles (checkpoints, landmines) prevent caregivers from pursuing the family's livelihood activities (such as accessing fields and livestock grazing lands).[4,5] Infrastructure such as health facilities, markets, water supply and sewage systems, schools and roads may be damaged or otherwise inaccessible.[4,5] Supply chains for food imports and essential medicines are often disrupted.[4,5] Populations may be forced to leave a conflict zone which could expose them to inadequate shelter, water, sanitation, and food and deprive them of livelihoods.[4,5] Displacement puts additional stress on host populations and their services and could increase population density.[5] Skilled healthcare and other personnel may leave the area and the most vulnerable households may be unable to do so.[5]

Most deaths due to conflict, particularly for children, are not from direct causes such as war-related trauma, but rather are due to the conditions that were already the main causes of death before the conflict including diarrheal disease, acute respiratory infections, measles, malaria, and severe malnutrition.[6] Therefore conflict seems to both exacerbate pre-existing health issues and introduce new ones.[6,7]

Malnutrition and diarrheal disease are two outcomes of particular interest in the study of child health and conflict because of their overall contribution to morbidity and mortality in the developing world and their sensitivity to disruptions commonly found in war zones such as increased food insecurity.[6] Malnutrition is a contributing condition in about 45% of all child deaths worldwide and in 60% of child deaths attributed to diarrheal disease.[8,9] Malnutrition and diarrheal disease form a vicious cycle of decreased energy intake and loss of micronutrients (due to lack of ingestion as the child weakens and intestinal malabsorption) and increased vulnerability to infection with the breakdown of mucosal barriers and immune system dysfunction.[9] In addition to short-term risks of illness and death, long-term consequences can include impaired physical and intellectual development and higher risk for metabolic and cardiovascular disease.[10,11]

Malnutrition is usually assessed using body measurements such as weight and height in combination with age and sex to determine growth or failure to grow.[12] A child's measurements are compared to a reference population to determine whether he or she falls outside of the expected distribution for any one of several anthropometric measures and if so, by how many standard deviations. A z-score (or standard deviation score) is the difference between an individual child's value and the expected value of the reference population. A child is classified as moderately malnourished if he or she is more than 2 standard deviations below average and severely malnourished if he or she is more than 3 standard deviations below average.[12] The World Health Organization reference standards introduced in 2006 are the most commonly used today.[13,14] These standards are based on optimally fed children of different ethnic and regional origins. They are predicated on the assumption - confirmed by numerous studies - that the distribution of basic nutrition scores for healthy, well-nourished children is similar in most human populations.[13]

In acute emergencies where local capacities are overwhelmed, the preferred measure of malnutrition is weight-for-height because weight is sensitive to sudden changes in food availability.[4,7,15] Height-for-age, which develops over the life of the child may be a more appropriate measure for chronic food insecurity.[7] Weight-for-age reflects both acute and chronic nutritional deficits, but is considered less useful than the other indicators.[11]

A summary of these three most common measures of malnutrition in children are shown in Table 4.1, below:

Measure	Condition	Notes	Classification (z-scores compared to reference standards)	
Weight-forHeight (WH)	Wasting	▪ Wasted children are thin for their height ▪ Result of recent rapid weight loss or failure to gain weight due to acute infection and/or inadequate dietary intake ▪ Reversible if conditions improve ▪ Evidence of acute malnutrition	Moderate wasting < -2 but > -3	Severe wasting < -3
Height-for-Age (HA)	Stunting	▪ Stunted children are short for their age ▪ A slow and cumulative process due to inadequate nutrition, repeated infection, or both ▪ Not an indicator of current health and nutrition status, as growth failure may have occurred in the past ▪ May be irreversible after about two years of age ▪ Evidence of chronic malnutrition	Moderate stunting < -2 but > -3	Severe stunting < -3
Weight-for-Age (WA)	Underweight	▪ Underweight children are light for their age ▪ Due to wasting, stunting, or a combination of both	Moderate underweight < -2 but > -3	Severe underweight < -3
* Children with nutritional edema – retained fluid which can contribute up to 50% of a child's weight - are always classified as severely malnourished (i.e., < -3 weight-for-height regardless of actual weight)				

Table 4.1: Summary of malnutrition measures. Adapted from UNICEF.[12]

The effects of war on child health are often studied through household surveys either in real time or retrospectively. In one of a series of mortality surveys in the Democratic Republic of Congo, a strong association between conflict and both violent and non-violent deaths was found.[16] In conflict and non-conflict areas of the country, the main reported causes of death were fever and malaria, diarrheal disease, and respiratory infections.[16] Children are most vulnerable to these diseases and those under five had nearly four times the risk of dying than people five and older.[16] Malnutrition was reported as an underlying or primary

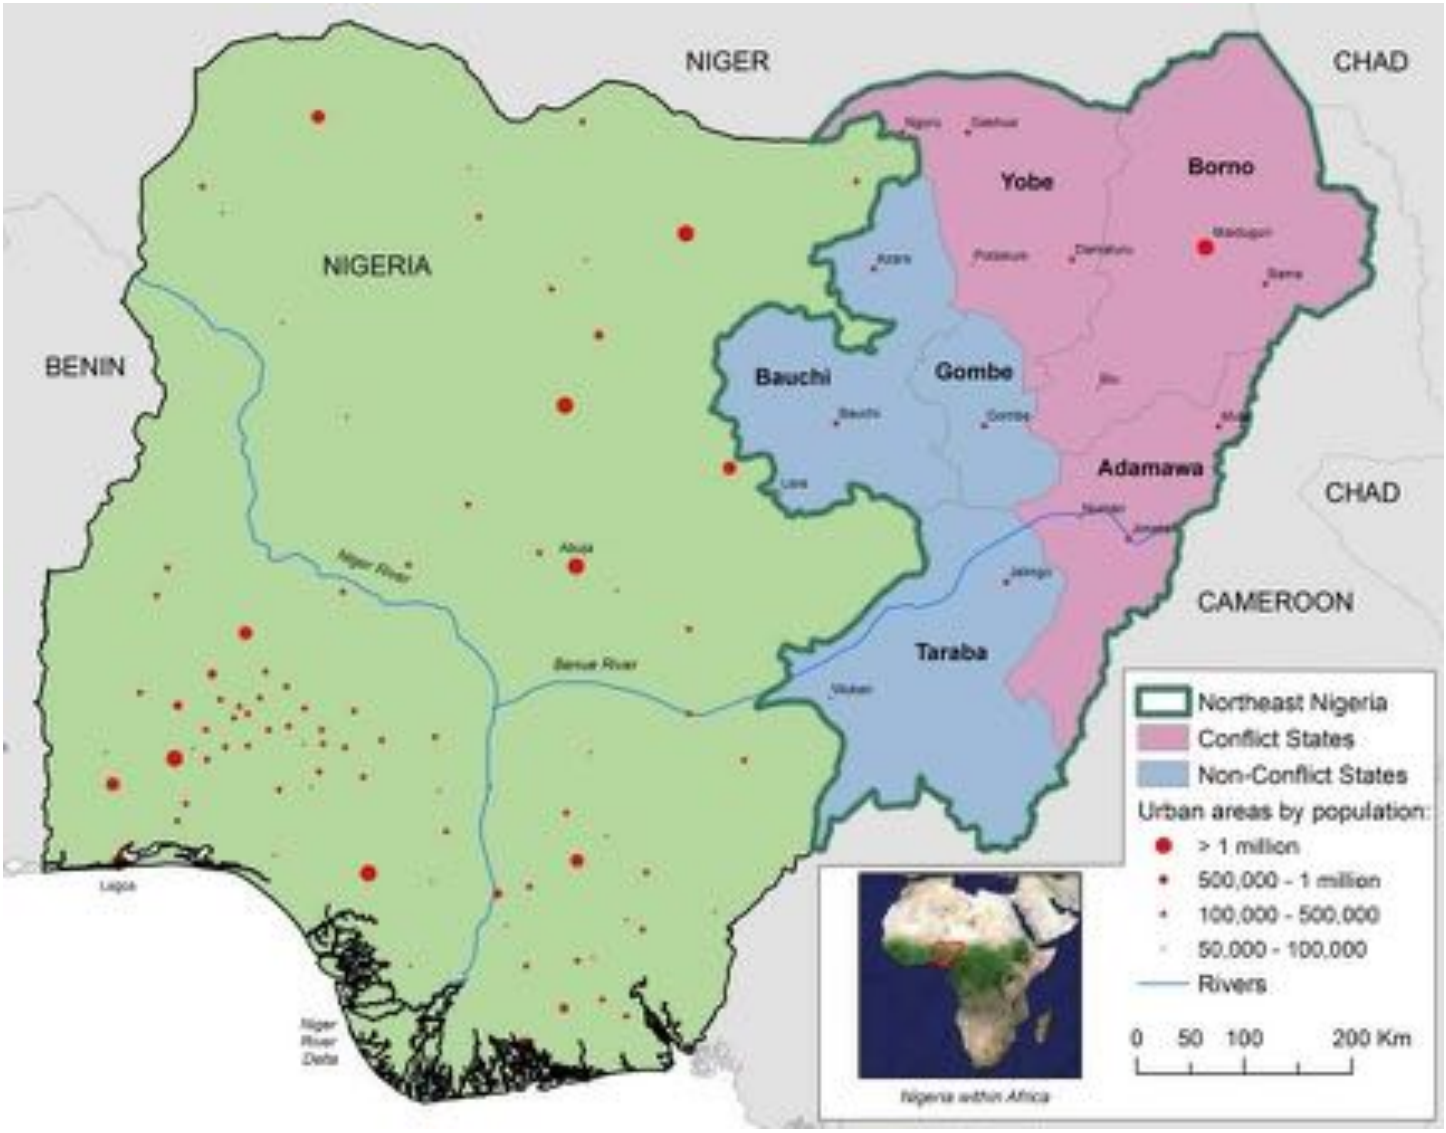
cause of death in 10.9% of deaths in conflict areas and 8.1% in non-conflict areas.[16] In Burundi, the civil war of the 1990s was marked by displacement, looting of household assets (including livestock), and the theft or burning of crops.[17] Using a spatiotemporal conflict exposure variable, researchers found that rural children who had been exposed to war for more than 14.7 months (the average exposure time) had height-for-age zscores 0.67 standard deviations lower than rural children who had not experienced war ($p < 0.01$).[17]

Additionally, for every month of exposure, height-for-age z-scores decreased by 0.05 standard deviations.[17] A study in Angola found higher levels of malnutrition (wasting and stunting) in conflict-affected areas and among assumed supporters of the opposition (determined by ethnolinguistic group), even after controlling for urbanrural and other demographic differences.[7]

This study contributes to the literature on conflict and child health by examining the associations between the recent conflict in Northeast Nigeria and the prevalence of malnutrition and diarrheal disease. The hypothesis is that malnutrition and diarrhea rates will be similar in conflict areas and non-conflict areas before the start of the insurgency with a generally improving trend over time, but that rates will increase in conflict areas after the start of the insurgency while maintaining a general downward trajectory in non-conflict areas. Furthermore, it is hypothesized that an estimation of the counterfactual – the average outcome for conflictaffected children if they had not been affected - will show improvements through increased z-scores (closer to the global average) and reduced rates of moderate/severe malnutrition and diarrhea. Weight-for-height and diarrhea prevalence are expected to show the largest effect because these outcomes are sensitive to acute emergencies, while the effects for height-for-age and weight-for-age may not be as evident.

Nigeria and Boko Haram

Nigeria is Africa's most populous country and among its most diverse with over 400 ethnolinguistic groups.[18] The country is affected by several conflicts based on overlapping ethnic, religious, political and regional divisions including over resources in the Niger Delta, Christian-Muslim divides in the middle of the country, and most recently, the rise of Islamist groups in the north, most importantly, Boko Haram.[18] Boko Haram ('Western education is a sin') was founded around 2002 in Maiduguri, the capital of Borno state and largest city in Northeast Nigeria (Figure 4.1).[19] At least at its inception, the main tenet among its followers was regime change in Nigeria as they believe democratic and secular rule is in contradiction to *Shariah* – a way of life for Muslims based on the Quran and the teachings of the Prophet Muhammad.[19]



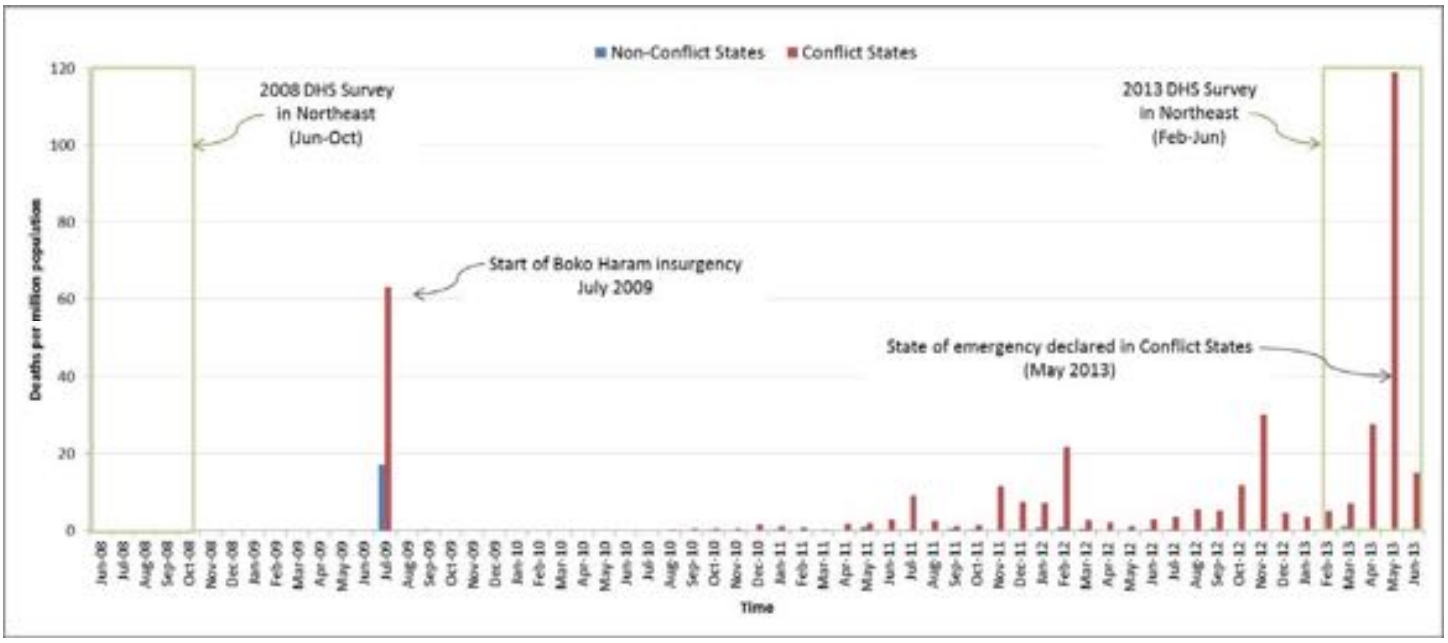


Figure 4.1: Northeast Nigeria with conflict and non-conflict states.

In July 2009, the Boko Haram uprising began in Bauchi and spread to other northern states, leaving hundreds of followers, Nigerian law enforcement officers, and civilians dead.[20] The leader of Boko Haram was captured and killed while in police custody in what is widely believed to be an extrajudicial execution.[20] The uprising left Boko Haram without a leader, drove the organization underground, and marginalized more peace-seeking members which eventually lead to radicalization and splinter groups such as Ansaru which have a purely combatant mandate.[19] The following year, a new leader took over Boko Haram, and attacks in the Northeast and other parts of the country including bombings, mass shootings, and executions began to rise.[20] In May 2013 the president declared a state of emergency in the states of Borno, Yobe, and Adamawa and deployed large numbers of troops to quash Boko Haram.[20] By November 2013, The US State Department had designated Boko Haram and Ansaru as Foreign Terrorist Organizations, but it was when 276 girls were abducted from their school in Chibok, Borno State in April 2014 that this conflict gained international attention.[20]

Figure 4.2 shows a timeline of these events using violent deaths attributed to events involving Boko Haram as a proxy for the intensity of the conflict. There are many indirect effects on the civilian population and these deaths include combatants on both sides, but the objective here is to distinguish between Borno, Yobe, and Adamawa as the affected group - called “conflict states” - and Bauchi, Gombe, and Taraba as the comparison group - “non-conflict states”. People in the non-conflict states have certainly been affected by the crisis, but the entire population of Borno, Yobe, and Adamawa states are considered directly impacted by the Boko Haram insurgency.[21] The timeline also shows July 2009 as a hard date for the start of the crisis in its current violent form.[22] This serves as the demarcation between pre-intervention and post-intervention for this study.

[23]

Figure 4.2: Timeline of deaths attributed to events involving Boko Haram in Northeast Nigeria. Data from Nigeria Watch.

At the start of the conflict, little was known about disruptions and displacement in the most affected areas. For example, as of August 2015, there were 1.4 million displaced people within the Northeast (1.3 million of whom were in the conflict states) and 170,000 refugees. In July 2013, however, little was known about internal displacement, although 9,000 refugees had already left Northeast Nigeria for neighboring countries.[18,21]

As a whole, northern Nigeria is poorer than southern areas and even before the conflict, the states of the Northeast ranked below the southern states on most socioeconomic indicators.[21] Food insecurity in Nigeria is attributed to high food prices (especially in urban areas) and a lack of agricultural input and drought in rural areas (in Northeast Nigeria, 28% of food is produced by the household – the highest rate in the country).[24] Access to health care is historically difficult due to poverty and distance to facilities.[25] Education, which already had low achievement indicators compared to the rest of the country, has suffered even more with attacks on schools, abductions, and forced recruitment of children since 2012.[26]

4.2 Methods

Data

This study uses data from two Demographic and Health Surveys (DHS), one of which was conducted in Nigeria in 2008 and the other in 2013 (Figure 4.2).[27] The DHS are large, nationally representative household surveys which have been conducted in low- and middle-income countries since 1984.[27] The DHS uses a two-stage sampling methodology.[28] The country is first stratified by geographic (usually administrative) regions crossed with urban or rural designation.[28] In each stratum, enumeration areas determined by the most recent census are used.[28] In the first stage, a number of primary sampling units are selected from the enumeration areas in each stratum.[28] The household lists in these areas are updated, and a fixed number of households are selected.[28] All household members within a specific group (relevant here is all women age 15-49) in the selected households are chosen for the survey.[28] Those women with children age 0-59 months are asked about the health and care of their children and the children are measured and weighed.[27] Only those children who were alive at the time of the survey are included in this analysis.

The outcome variables of interest are malnutrition and diarrhea. Malnutrition is measured both as a continuous variable using z-scores for weight-for-height (WHZ), height-for-age (HAZ), and weight-for-age (WAZ) and as a binary outcome (moderate/severe wasted or not, moderate/severe stunted or not, and moderate/severe underweight or not). Diarrhea is a binary variable of whether the child has had diarrhea in the past 2 weeks or not. As per WHO guidelines, data were excluded if a child's WHZ was below –5 or above +5, HAZ was below –6 or above +6, or WAZ was below –6 or above +5, because these extreme values were most likely a result of errors in measurement or data entry.[13]

In addition to exposure to conflict, explanatory covariables include characteristics related to the environment, household, caregivers, and individual child as detailed below.

Environmental factors are:

- The month of the interview. This is used to control for seasonal effects of the survey as the rainy
- season starts in about May and runs through September in the Northeast, after which there is extremely little rainfall. The rainy season is a key factor for primary food production for rural populations.
- Altitude, which ranges from about 100 to 1,500 meters for the sample population. Altitude may determine livelihoods and remoteness of populations.
- Urban/rural designation. Esri's "populated places" dataset was used rather than the DHS classification as it is slightly more restrictive, using urban centers of only 50,000 people or more.[29]
- Urban population rank. Also from the Esri dataset; classified as urban centers of population 50,000100,000; 100,000-500,000; 500,000-1 million; or greater than 1 million.[29] In the Northeast, there are no cities in the 500,000-1 million category and only one (Maiduguri) above 1 million. Also, by 2013, the smaller cities had transitioned to medium ones.

Household characteristics are:

- Wealth as determined by an index which accounts for the assets and services available to a household.[30] For this analysis, a binary variable was created for whether the household was in the bottom two wealth quintiles (poorest households) or not.
- Water source and toilet type. These factors were classified as either "improved" or "unimproved" as per the WHO/UNICEF Joint Monitoring Programme for Water Supply and Sanitation (JMP) classification scheme.[31] Water and sanitation are part of the wealth index, but showed little collinearity for this dataset (VIF = 1.15 – 1.35).

- Number of people in household, which can have a positive effect on child health (many caregivers) or negative (stretched resources). For this reason, this term was also squared.
- Number of children under five and this term squared. Similar to the variable above, a household with many children may show pooled resources, but can also mean at least some of the children do not get the attention or resources they need.[32]

Caregiver (child's mother and mother's partner) characteristics include:

- Occupation, which is classified here as either in agriculture/not working or other. "Not working" is included because - especially for women - this means "not outside the home". Combined with the wealth index, this gives an indication of subsistence farming/pastoralism vs. reliance on outside wages.
- Educational attainment, here as a binary variable of no formal education or some education (primary, secondary, or higher). Attending a *madrasa* or other religious school is considered having no formal education in the Nigeria DHS.[33]
- Mother's religion, classified as Muslim or other (Christian or traditionalist).

Child characteristics are:

- Age in months. The term is also squared as, for example, stunting occurs primarily *in utero* and during the first 2-3 years of life.[34]
- Sex, as several studies show slight differences in malnutrition outcomes between boys and girls.[35,36]
- Birth order, also squared as for some health outcomes, higher birth orders may be protective up to a certain limit due to the experience of the mother and the help older siblings may provide in basic childcare.[32]

Double-Difference (DD) analysis

Double-difference (also known as difference-in-difference) analysis is a popular methodology to estimate the causal effects of policies or programs.[37] It is a quasi-experimental design which makes use of before and after groups, but without random assignment.[38] Double-difference (DD) analysis has been used at least once to study the effects of conflict (on education in Côte d'Ivoire) and on malnutrition (as a result of migration patterns in Guatemala).[34,39] The calculations and interpretations are relatively straightforward and the endogeneity problems that typically arise when making comparisons between heterogeneous individuals can potentially be avoided.[40] In DD analysis, first a time- and population-specific intervention such as the introduction of a policy or the inception of a new program is identified. Then the difference in outcomes after and before the intervention for those affected by the intervention are compared to the difference in outcomes after and before the intervention among those not affected by the intervention.

This can be written as:

DD = [(Intervention = 1 | Period = 1) - (Intervention = 1 | Period = 0)] - [(Intervention = 0 | Period = 1) - (Intervention = 0 | Period = 0)]

The DD approach is most frequently used within a linear regression model with a continuous outcome variable to which covariates may be added. In this study, the intervention is conflict and the model may be written as:

$$y = \beta_0 + \beta_1 * Conflict + \beta_2 * Period + \beta_3 * (Conflict * Period) + \beta_k * (environmental, household, caregiver, and\ child\ covariates) + \varepsilon$$

where the outcome variable *y* is the mean z-score, *Conflict* is a dummy variable coded 0 for conflict states and 1 for non-conflict states and *Period* is a dummy variable coded 0 for 2008 and 1 for 2013. The main coefficient of interest is β_3 - the interaction term of *Conflict* and *Period* - which is the estimate of the effect of the double difference. B_k represents the coefficients for covariates included in the model and ε is the error term. Note that for most DD analyses, exposure to the intervention would be coded 1; however here, we are interested in

what the outcome would have been for the exposed group (children in a conflict zone) had they *not* been exposed. Therefore the reverse coding is necessary to obtain the correct sign for the interaction coefficient.

In addition to any differences in mean z-scores, it is important to know if there are any changes in the likelihood that a child will be in the most vulnerable group – moderately or severely malnourished children. For this, logistic regression is used, which also allows for testing the likelihood that a child will have diarrheal disease or not. An advantage to the logistic model is that the marginal effects of the conflict can vary according to the characteristics of the individual child.[41] However, calculating the marginal effects of an interacted term such as the DD coefficient is not straightforward in non-linear models.[42] To facilitate this calculation, the user-written Stata command *inteff*, which computes the correct marginal effect for the interaction term as well as the standard errors and z-statistic, is used.[42]

The fundamental assumption of DD analysis is that of common (or parallel) trends.[43] In the language of this study, common trends means that if the Boko Haram insurgency had not started, the difference in child health outcomes in the conflict states and non-conflict states would be constant over time. In other words, in the absence of the conflict, children throughout the Northeast would be on a similar path (improving, worsening, or staying the same), *ceteris paribus*. If this assumption is not fulfilled, any estimation of the causal effect of the conflict will be biased.

Common trends is tested by examining earlier data, if possible. The DHS program conducted two surveys in Nigeria in 1990 and 2003 and these data were analyzed with the 2008 and 2013 data. First, proportions of moderate/severe wasting, stunting, and underweight and diarrhea were calculated without covariates. Then, to account for seasonal differences in the surveys, the month variable was included.[44] This was conducted in

Stata with the user-written command *svypxcat*, which calculates covariate-adjusted proportions corrected for survey weights.[45]

The 1990 and 2003 DHS surveys were at the zone (e.g., Northeast) level so the GPS coordinates of the sampling points were used to determine states. These earlier surveys also used a different nutrition reference standard, so the raw height and weight data were used to calculate the z-scores with the WHO standards using the Stata user-written command *zscore06*.[46]

After examining the results of the common trends analysis, it was determined which outcomes should be included in the linear and logistic regression models. These were conducted in Stata 14.1 first without any covariates, and then adjusted with the environmental, household, caregiver, and child characteristics.[47] Because the *inteff* command allows for continuous and indicator (0/1) variables, but not categorical ones, urban population was converted to an indicator variable for the logistic model.

4.3 Results

Population description

Descriptive statistics for the 2008 and 2013 populations are shown below for explanatory variables (Table 4.2) and health outcomes (Table 4.3). There are few missing observations for the explanatory variables, but the number is significant for malnutrition due to the challenges of field work and obtaining complete and credible measurements.[25,48]

The two surveys were done at different times of the year; during the entire rainy season in 2008 and spanning the dry season and start of the rainy season in 2013. Overall, the conflict states are more urbanized, mostly due to the presence of Maiduguri, where the proportion of the population grew from 7 to 13% between the

two surveys. The proportion of households in the wealthier three quintiles grew in the Northeast between 2008 and 2013, but unevenly; 10% in conflict states, but with no proportional change in the non-conflict states. Similarly, the average increase in access to improved water sources and toilet types from 2008-2013 was from 34 to 45%, but with a larger increase in the conflict states (water 18%, toilet 12%) vs. non-conflict states (water 10%, toilet 3%). Education rates are low in the Northeast; 72% of mothers and 60% of their partners have no formal education. About 85% of the population is Muslim.

While moderate or severe wasting declined in the non-conflict states by 10%, the proportion increased in the conflict states from 18 to 23%. There was a steep decline in the proportion of children with moderate or severe stunting in the conflict states from 49% to 36% while there was virtually no change in the non-conflict states. Proportions for moderate or severe underweight and diarrhea prevalence declined equally for conflict and non-conflict states; about 4% and 2%, respectively.

Table 4.3: Number and proportions of health outcomes in conflict and non-conflict states of Northeast Nigeria, 2008 and 2013.

Common trends

There is no statistical test for common trends analysis, but visualization such as in Figure 4.3 is helpful for discerning patterns. Including the month of household interview term makes the trends more parallel for wasting and underweight, but not for stunting. This is logical, especially in rural areas where a child's weight may change quickly from season to season. This effect would not necessarily be seen with stunting, as that is a cumulative process over years. The trend for diarrhea prevalence changes slightly, most importantly, the slight upward tick from 2008-2013 in the unadjusted model becomes a downward trend in the adjusted model. Seasonal effects of diarrhea can be complex in sub-Saharan Africa. For example, increased rains can

contaminate water supplies, but the dry season can also concentrate pathogens, increase fly activity, and lead to poorer hygiene and food security.[49-52]

Wasting, underweight, and diarrhea prevalence fulfilled the common trends requirements. For wasting, the trends are similar before the start of the conflict and then diverge after the start of the conflict, so there is likely a significant double-difference estimate. For underweight, the trends are nearly parallel, and remain so after the start of the conflict, so any double-difference estimate is likely to be statistically insignificant. For diarrhea prevalence, after the start of the conflict, the rate of diarrhea declines in both conflict and nonconflict states, but apparently at a slower rate in the conflict states; thus there may be a statistically significant double-difference estimate. Stunting shows a nearly complete divergence of trends, indicating any doubledifference would not be valid, even if it was statistically significant because the result could not be attributed to the start of the conflict.

Based on these results, further analysis and discussions will focus on weight-for-height and wasting, weightfor-age and underweight, and diarrhea prevalence. For completeness, the results for height-for-age and stunting are shown in the Appendix and will be included in the discussion.

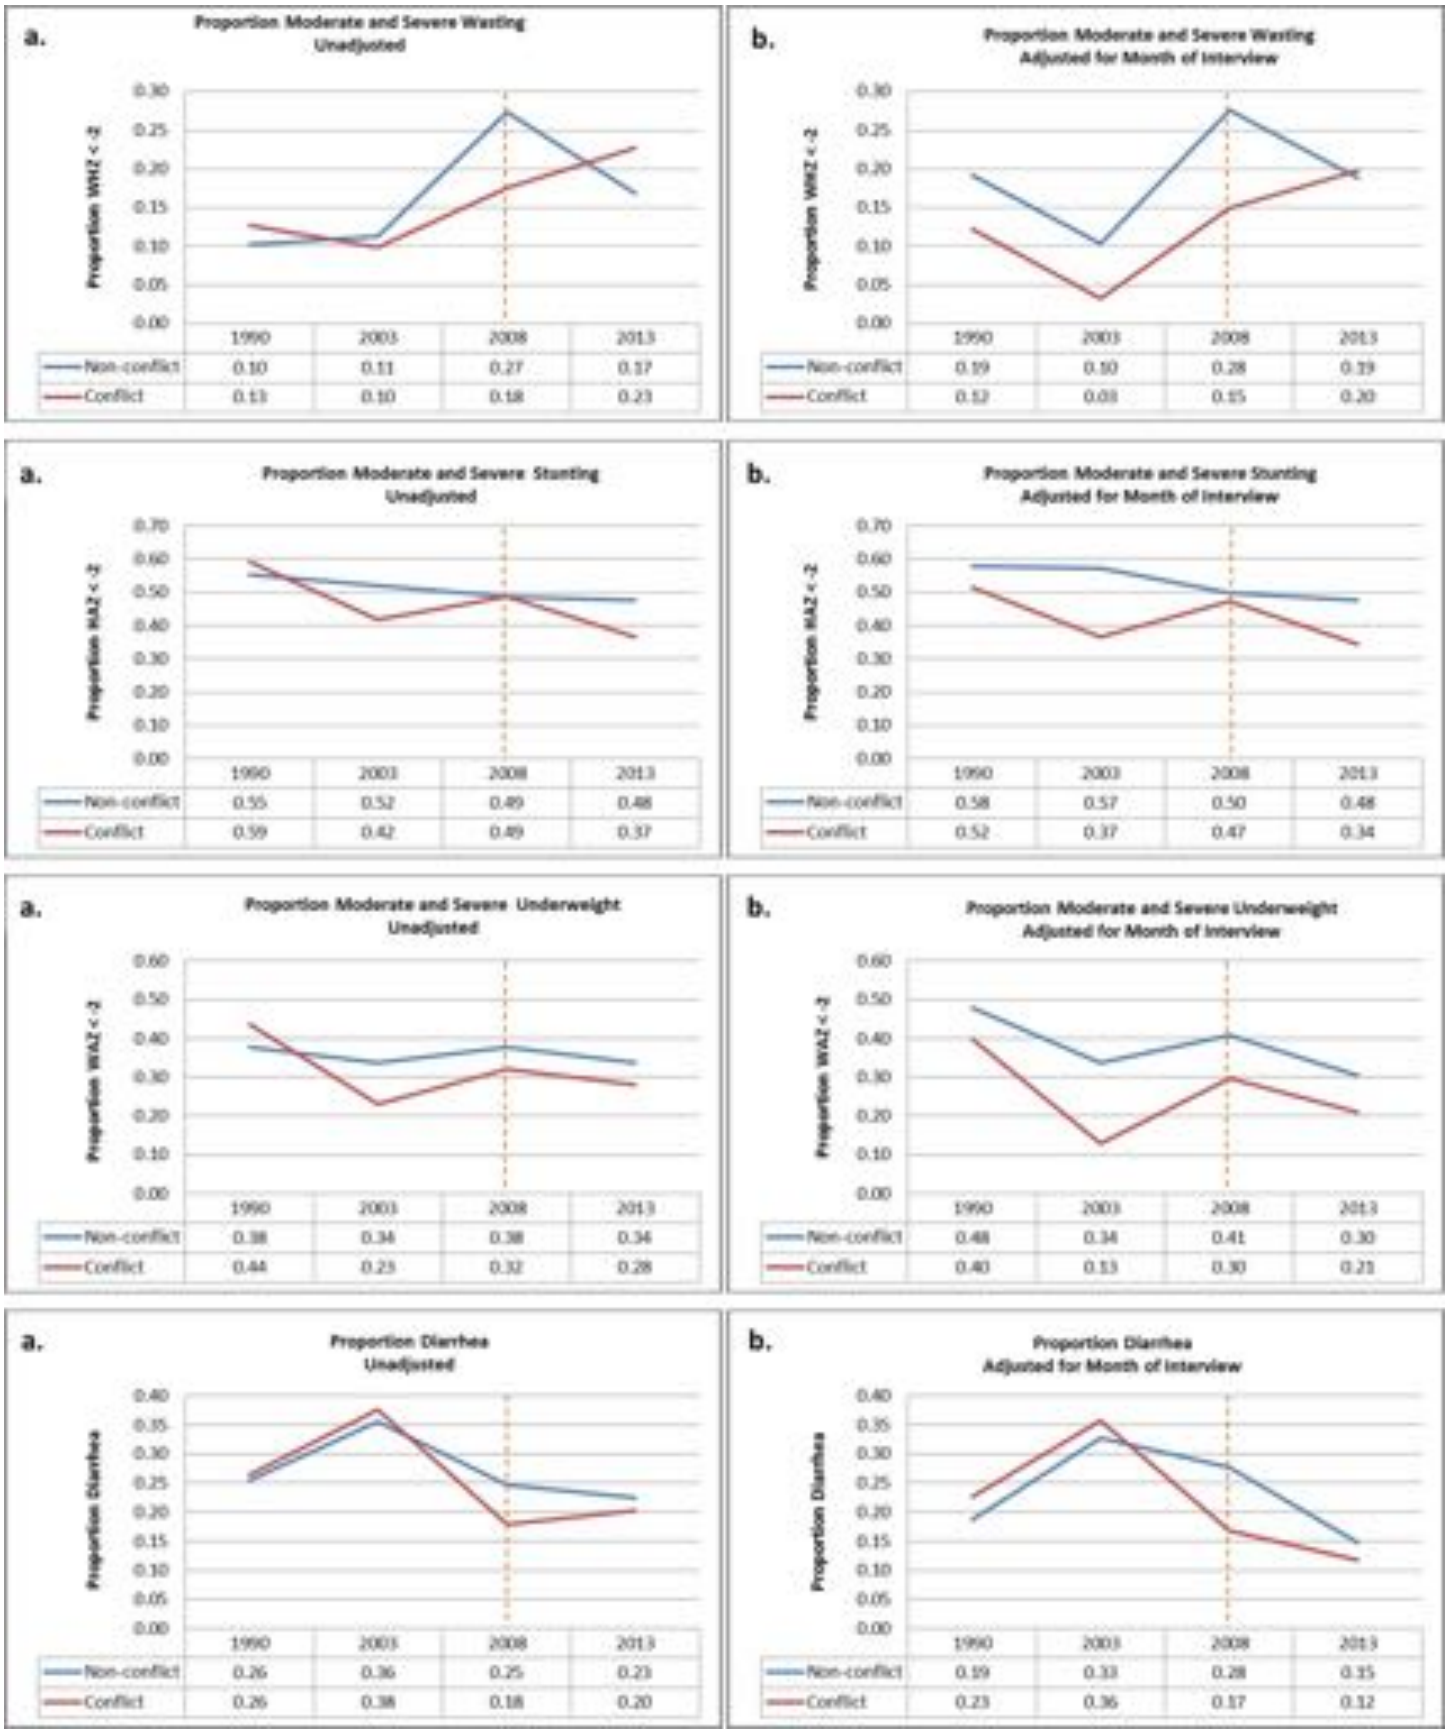

Figure 4.3: Trends in malnutrition and diarrheal disease in Northeast Nigeria's conflict and non-conflict states: (a) panels are raw proportions, (b) panels are proportions adjusted for month of household interview. Dotted orange line is the time point between the 2008 and 2013 surveys.

Weight-for-height z-scores

The results of the linear regression for weight-for-height z-scores are shown in Table 4.4. Model 1 is without covariates and Model 2 has all environmental, household, and child covariates. Model 3 has select covariates based on their significance in Model 2. The main coefficient of interest is "double-difference", which is highly significant in all the models. The results suggest that, *ceteris paribus*, if children who were exposed to the Boko Haram insurgency had not been exposed, their mean weight-for-height z-scores would be 0.49 standard deviations higher than they are ($p < 0.001$). More variance can be explained with the addition of covariates to Model 1 and the main difference between Model 2 and Model 3 is that the intercept increases from -0.40 to 0.27. On average, z-scores increase if the interview was conducted in the rainy season compared to the dry season. Altitude has a small, but significant effect with z-scores decreasing slightly for every meter gain in elevation. Urban/rural classifications were not statistically significant, although the size of urban center was. Specifically, children in Maiduguri had an average weight-for-height z-score 0.72 standard deviations higher than children living in small cities. Wealth was marginally significant, but the other household variables were not. Compared to children whose mothers had at least some education, those whose mothers had no formal education had lower weight-for-height z-scores by an average of 0.13 standard deviations. Children of Muslim mothers had an average weight-for-height z-score 0.29 standard deviations lower than children of other religions (94% of whom are Christian). Z-scores decreased slightly for every additional month of age and boys had slightly lower z-scores than girls.

Table 4.4: Results of linear regression for weight-for-height z-scores. Model 1 has no covariates, Model 2 includes all environmental, household, caregiver, and child covariates, Model 3 has select covariates based on significance in Model 2.

Moderate or severe wasting

Table 4.5 shows the corrected marginal effects for the interaction term, which is the estimate of the doubledifference for the probability of moderate or severe wasting. Model 1 is without covariates, Model 2 has all environmental, household, and child covariates, and Model 3 has select covariates based on their significance in Model 2. The results suggest that, *ceteris paribus*, if children who were exposed to the Boko

Haram insurgency had not been exposed, the likelihood of moderate or severe wasting would decrease by 13 percentage points. The DD estimation from the logistic model before correction – about 87 percentage points - is also shown. Figure 4.4 shows these results graphically, illustrating that there is some variance in the marginal effects of the conflict on individual children, but that the overall pattern is similar. The results are statistically significant for nearly all the individual children (mean z-statistic = -4.2).

Table 4.5: Corrected marginal effects for the interaction term (double-difference) for moderate or severe wasting. The uncorrected interaction term is also shown for comparison. Model 1 has no covariates, Model 2 includes all environmental, household, caregiver, and child covariates, Model 3 has select covariates based on significance in Model 2.

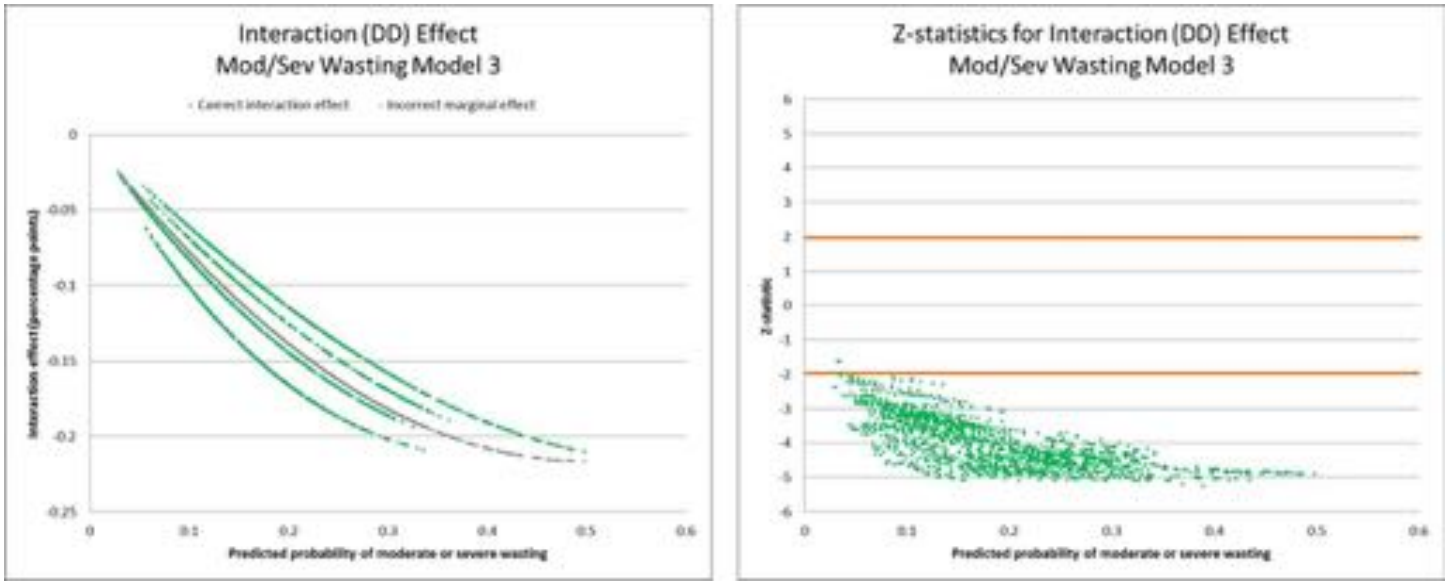

Figure 4.4: Graphic representation of incorrect and corrected marginal effects for the interaction term (double-difference) for moderate or severe wasting, Model 3 with select covariates. Left panel is the interaction effect and right panel is z-statistics for individual children.

The covariates for the logistic regression model are shown in Table 4.6, expressed as odds ratios. Overall, the effect of month of interview is more protective in the dry months (February decreased odds of 43%) than in

the wetter months (August decreased odds of 34%). Higher altitude increases the odds slightly. Living in Maiduguri decreased the odds of moderate or severe wasting by 63% compared to living elsewhere. Both the mother's and her partner's education are significant in the final model with no formal education increasing the odds of moderate or severe wasting by 22%. If the mother is Muslim, the odds increase by 34%. The age and sex of the child is not significant for this outcome.

Table 4.6: Odds ratios (OR), p-values, and standard errors for covariates of logistic regression for moderate or severe wasting. Model 1 has no covariates, Model 2 includes all environmental, household, caregiver, and child covariates, Model 3 has select covariates based on significance in Model 2.

Weight-for-age z-scores

The results of the linear regression for weight-for-height z-scores are shown in Table 4.7. Model 1 is without covariates and Model 2 has all environmental, household, and child covariates. Model 3 has select covariates based on their significance in Model 2. As expected from the common trends analysis, the double-difference coefficient (0.02) is not statistically significant in the final model (p-value 0.9).

Table 4.7: Results of linear regression for weight-for-age z-scores. Model 1 has no covariates, Model 2 includes all environmental, household, caregiver, and child covariates, Model 3 has select covariates based on significance in Model 2.

Moderate or severe underweight

Table 4.8 shows the corrected marginal effects for the interaction term, which is the estimate of the doubledifference for the probability of moderate or severe underweight. Model 1 is without covariates, Model 2 has all environmental, household, and child covariates, and Model 3 has select covariates based on their significance in Model 2. Also as expected from the common trends analysis, the double-difference estimate of -0.03 is not statistically significant for any individual child (mean z-statistic range -1.8 to -0.3). Figure 4.5 shows these results graphically, and the odds ratios for the covariates are shown in Table 4.9.

Table 4.9: Odds ratios (OR) for covariates of logistic regression for moderate or severe underweight. Model 1 has no covariates, Model 2 includes all environmental, household, caregiver, and child covariates, Model 3 has select covariates based on significance in Model 2.

Diarrhea prevalence

Table 4.10 shows the corrected marginal effects for the interaction term, which is the estimate of the doubledifference for the probability of diarrhea. Model 1 is without covariates, Model 2 has all environmental, household, and child covariates, and Model 3 has select covariates based on their significance in Model 2. The results suggest that, *ceteris paribus*, if children who were exposed to the Boko Haram insurgency had not been exposed, the likelihood of diarrhea would decrease by 8 percentage points. The DD estimation from the logistic model before correction – about 44 percentage points - is also shown. Figure 4.6 shows these results graphically, illustrating that there is some variance in the marginal effects of the conflict on individual children, but that the overall pattern is similar. The results are statistically significant for all the individual children (mean z-statistic = -3.3; max z-statistic -2.0).

Table 4.10: Corrected marginal effects for the interaction term (double-difference) for diarrhea prevalence. The uncorrected interaction term is also shown for comparison. Model 1 has no covariates, Model 2 includes all environmental, household, caregiver, and child covariates, Model 3 has select covariates based on significance in Model 2.

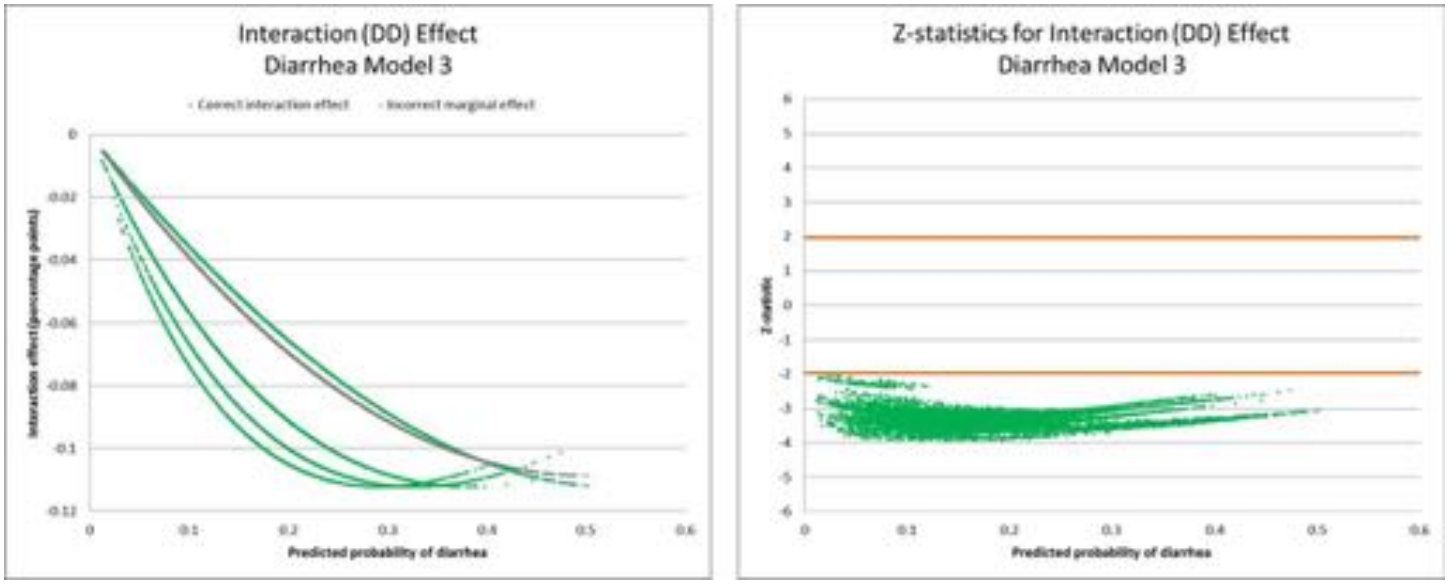

Figure 4.6: Graphic representation of incorrect and corrected marginal effects for the interaction term (double-difference) for diarrhea prevalence, Model 3 with select covariates. Left panel is the interaction effect and right panel is z-statistics for individual children.

The odds ratios for the covariates are shown in Table 4.11. Overall, the effect of month of interview is more protective in the months with generally higher rainfall (October decreased odds of 57%) than in the drier months (August decreased odds of 3%). Altitude was not significant in the final model. Compared to children in households in the wealthier three quintiles, children in households in the poorer two quintiles had increased odds of 38%. Improved water sources decreased odds by 12%, while toilet type was not significant. Here, both the mother's and her partner's occupation are significant, decreasing the odds of diarrhea by 23% and 17%, respectively, but their educational attainment is not significant in this model. Similar to wasting, if the mother is Muslim, the odds of diarrhea increase by 31%. Age is significant for diarrhea, with 5% increasing risk for every additional month. Boys had about 11% higher odds of diarrhea than girls.

4.4 Discussion

This study finds significant double-difference estimates for average weight-for-height z-scores, prevalence of moderate or severe wasting, and prevalence of diarrhea. In a counterfactual scenario where children exposed to the Boko Haram conflict had not been exposed, the estimates indicate there would have been improved health outcomes for these measures. Because of potential unidentified confounding, this research cannot conclude that the conflict caused negative health outcomes; however, it does demonstrate that the children exposed to the conflict had a different and detrimental experience compared to children not exposed to the conflict.

Non-significant double-difference estimates were found for average weight-for-age z-scores and prevalence of moderate or severe underweight. Double-difference analysis was found to not be appropriate for these data for height-for-age or moderate or severe stunting.

This research suggests that if children who were affected by the Boko Haram insurgency in Northeast Nigeria had not experienced the conflict, they would have weight-for-height z-scores an estimated 0.49 standard deviations higher than they are. This would be a significant improvement; in 2013, the average weight-forheight z-score in the Northeast was -0.69 (SD 1.62) and in the conflict states it was -0.74 (SD 1.8). For children already in the range of normal weight-for-height (generally -1 to +2 standard deviations from the reference population), this would not be a large difference. However for marginally wasted children (-1 to -2 SD) and especially vulnerable children below -2 standard deviations, this increase would mean better short-term health, increased resistance to other illnesses, and reduced risk of mortality. It should be noted that increased z-scores are generally a positive sign in the developing world; however, overweight and obesity is a growing concern.[53] In this area, about 7% of children are classified as high range weight-for height (+2 SD or more).

The weight-for-height models have several significant coefficients, but low r-squared terms, which indicate that the data have high variability but that the explanatory covariables still provide information about the outcome. Thus, while these models have little predictive precision, the objective of the analysis – to determine whether there are before-after effects due to conflict – is accomplished.

This analysis also estimates with a high degree of significance that the prevalence of moderate or severe wasting would have been 13 percentage points lower in the absence of conflict in Northeast Nigeria. This too would be an important difference, bringing the proportion down from 23% to 10%, where the average proportion for all of West Africa is 9%.[54,55] This would reduce the proportion of children at risk of dying from malnutrition and co-morbidities and would help ensure a healthier and more productive adult population in the future.

In terms of international guidelines, the absence of conflict in Northeast Nigeria would move the nutritional crisis there from "serious" to "poor" for average z-scores and from "critical" to "serious" for prevalence of moderate or severe wasting (see Table 4.12).

Severity of Nutritional Crisis	Mean weight-for-height z-score	Prevalence of moderate or severe wasting
Acceptable	> -0.40	< 5%
Poor	-0.40 to -0.69	5 – 9%
Serious	-0.70 to -0.99	10 – 14%
Critical	≤ -1.00	≥ 15%

Table 4.12: Nutritional crisis classifications. Adapted from the World health Organization (2000).[54]

The counterfactual scenario also holds true for diarrhea prevalence: if children who were affected by the Boko Haram insurgency in Northeast Nigeria had not experienced the conflict, their prevalence of diarrhea would have been 8 percentage points lower than it is. This would have brought the prevalence down from the current 20% in the conflict states to 12%, close to the national average of 10%.[25] This decrease would mean that children were not suffering from diarrheal episodes as often, but also that their gastrointestinal and immune systems were not being compromised, perhaps leading to fewer infections and better growth and development.

The reasons for how the conflict affected child nutrition and illness is not fully known, but news reports from around the time of the 2013 survey give some sense of the atmosphere in the conflict areas. There are reports of indiscriminate executions of ordinary people, suicide attacks killing scores of people in buses, the kidnapping of local and foreign civilians, the burning down of towns, and attacks on schools resulting in the deaths of students and teachers.[56] Men were fleeing forced conscription by Boko Haram and civilian groups formed to fight the insurgents.[56] There were several prison breaks at this time as police stations and military

patrols were bombed and Boko Haram commanders were killed.[56] After the state of emergency was declared, telephone service were shut down in Borno and Yobe.[56]

Reports from the Famine Early Warning Systems Network illustrate growing food insecurity during this time.[57] In March 2013, Yobe, Borno, Adamawa, and Taraba (a non-conflict state) were considered "stressed" due to population displacement and below average harvest yields.[57] Security measures such as checkpoints reduced population movements and increased transportation costs.[57] Traders and their customers were concerned about their safety in markets, which reduced food stocks and overall market functioning.[57] By the time the state of emergency was declared in May, Yobe and Borno states were elevated to "crisis" stage, as poor households faced depleted food stocks and acute food insecurity.[57]

From the perspective of 2016, this was the start of a worsening humanitarian crisis which is marked by fear, displacement, families split apart, disrupted services such as health care, schools, and maintenance of infrastructure, and limited access by local and international humanitarian assistance organizations, especially to more remote areas.[26] This led to a malnutrition crisis, which was already identified in February 2012 as food insecurity increased and childhood illnesses exacerbated by malnutrition went untreated in many cases.[26] Without these effects, children would have had more stability, improved nutrition, and better health.

In double-difference analysis, covariates are included to improve the models, but their coefficients are secondary in importance to the double-difference coefficient. However, the significant covariates in the regression models - month of interview, altitude, urban population, wealth, water source, occupation, education, religion, and age and sex of the child - also offer insight into what factors contributed to child health in this setting. For weight-for-height z-scores and diarrhea prevalence, the rainy season was more favorable, while for likelihood of moderate or severe wasting, the dry season was more favorable. This could

be due to different seasonal dynamics affecting the whole child population as opposed to the most vulnerable. A healthy child may gain weight if food security improves in the rainy season from a household garden, for example. But a child who is already marginally wasted from recent illness may lose weight by the end of the rainy season if last year's stores are low and this year's harvest is not yet in (often referred to as "the lean season"). This is consistent with findings that mortality often peaks at the end of the rainy season.[58] Additionally, diarrhea prevalence may decrease with moderate rainfall if water sources are plentiful and there is enough recharge to dilute pathogens. Increased altitude is consistent with poorer outcomes in both the linear and logistic regression models, perhaps reflecting better year-round food security in the lowest elevation areas where people fish in the Benue River as opposed to the less densely populated highlands where people rely on corn, sorghum and cash crops like cotton.[59] Urban/rural classification was not significant, but living in the largest city, Maiduguri, was protective for weight-for-height and moderate/severe wasting. This speaks to the dual role of Maiduguri as the stronghold of Boko Haram, but also as a place relatively conducive to child health. Sub-Saharan Africa has instances of both "urban advantage" and "urban disadvantage" – at least for this city and for weight-for-height, Maiduguri seems to fall in the former category.[60]

Most of the household variables were not significant in these analyses. In addition to the environmental variables, what seems to be more important are the characteristics of the mother and her partner (likely often the child's father). If the mother had some education, her children have significantly better weight-for-height and moderate/severe wasting outcomes, consistent with other studies.[2] In this population, among mothers with some education, the majority (56%) have only at least some primary schooling, which suggests even minimal education can make a difference in child health outcomes. For moderate/severe wasting, the partner's education also contributed to positive outcomes. This is a less studied field, but reflects the contribution of the partner whether directly or not, even after controlling for the mother's own education, on

a child's health.[61] For diarrhea, household wealth, both the mother and her partner's occupation, and water source were significant, indicating that children in poor, agriculture-dependent households that do not have reliable access to clean water are vulnerable to this disease. Having a Muslim mother lowered the average weight-for-height z-scores and increased the likelihood of moderate or severe wasting and diarrhea, indicating that although they are the majority population, children in Muslim families do not fare better than their Christian counterparts.

Age of the child is significant for weight-for-height z-scores (slightly decreasing average z-scores for an increase of one month in age) and diarrhea prevalence (slightly increasing odds with age). This could indicate that children are more vulnerable to food insecurity as they are weaned, and that overall, increasing exposure to pathogens as they become more independent makes them vulnerable to infection. Boys had slightly lower weight-for-height z-scores than girls and higher odds of diarrhea.

An important aspect of this study was to use common trends analysis to determine which outcomes would provide valid results with DD analysis. Height-for-age and stunting were deemed inappropriate for DD analysis as their diverging trends before the start of the insurgency means that there were other unobserved dynamics driving this outcome over time, independent of the conflict. For the purposes of completeness, the results are shown in the Appendix. As seen in the Appendix Table 4.1, the double-difference height-for-age z-score estimation is -0.60 and statistically significant, meaning children affected by conflict would have had *lower* zscores if there had been no conflict. Similarly, the double-difference estimate for moderate or severe stunting is positive (there would have been 8 percentage points *more* stunting in the absence of conflict) and significant (Appendix Table 4.2, Appendix Figure 4.1, and Appendix Table 4.3).

In addition to common trends, an assumption of DD analysis is that the intervention is not related to the outcome at the baseline period; i.e., the conflict was not driven by especially poor child health outcomes. While poverty is certainly a driving factor in the rise of Boko Haram, the conflict states are more prosperous than the non-conflict states as seen in the descriptive statistics (Table 4.2), so this assumption is largely met.[19] These findings support the original hypotheses regarding for weight-for-height, wasting, and diarrhea; that if children exposed to conflict had not been exposed, there would be significant improvements in terms of both z-scores and proportion with moderate/severe wasting or diarrhea. As hypothesized, findings were limited for weight-for-age/underweight and height-for-age/stunting. The trends before the crisis were not improving overall as hypothesized, likely because there were limited time periods.

There are several limitations associated with this study. Most importantly is that there is likely unidentified confounding where certain factors influence both conflict and health outcomes. Thus the associations between conflict and malnutrition/diarrhea found here should not be interpreted as causality. Another limitation is that Boko Haram is not the only cause of violence in the Northeast and there could be other unobserved dynamics that affect the results, for example what is referred to as inter-communal violence largely along religious affiliations.[18] This leads to the difficulties of finding an appropriate comparison group. Using the six states within the Northeast zone was chosen because this better preserved the sampling method of the surveys and the timing of the interviews is narrower. However, a future study could test the robustness of the results by using an alternative comparison group such as states in the Northwest.[25] There were limitations with the common trends analysis because were only two previous surveys; additional timepoints may have shown clearer trends, especially for stunting. The timing and content of the 2013 survey was both fortuitous and doubtless with its challenges. Interviewers were capturing real-time events in their data that likely reflect acute changes in child health, but they were perhaps impeded or rushed in some areas which may bias results. Although the number of weighted observations in 2013 is less than in 2008 (Table 4.3), the

percent of missing observations is actually less in 2013. Still, it is unknown whether the missing data for malnutrition biased the results. A specific point about the 2013 survey is that the displacement or migration history of households is not known. It is equally possible that those with means or that the most vulnerable left the Northeast or moved to Maiduguri, making the direction of any bias difficult to determine.[62] Also, DHS does not measure nutritional edema, which may lead to an underestimate of wasting and underweight (for example, among the 7% of children who are classified as high range weight-for-height).[63]

4.5 Conclusion

This study used double-difference (DD) methodology to estimate the effect of the Boko Haram insurgency in Northeast Nigeria on child malnutrition and diarrhea. The differences in outcomes among two groups – those in conflict and non-conflict areas and in two periods – before and after the start of the conflict – were compared using household survey data from the Demographic and Health Surveys. Visualization of common trends from 1990 through 2013 showed that weight-for-height/wasting, weight-for-age/underweight, and diarrhea prevalence outcomes were plausibly linked to the insurgency while height-for-age/stunting outcomes were not. Linear regression – the more typical model for DD analysis – using weight-for-height z-scores showed that in the counterfactual scenario where children affected by conflict were not affected by conflict, average z-scores would be 0.49 standard deviations higher. A logistic model to estimate the likelihood of moderate or severe wasting also finds improved results in the counterfactual scenario – a reduction by 13 percentage points of children in this high-risk category. Likewise, a logistic model to estimate the prevalence of diarrhea finds that in the absence of conflict, there would have been a reduction of 8 percentage points. These results bring child health outcomes closer to the national and sub-regional averages. The DD estimates were statistically significant without covariates, but their inclusion improves the model and shows the relative influence of factors such as the age and sex of the child, the education, occupation and religion of the mother, living in a major city, seasonality, and altitude on child health outcomes.

The counterfactual scenario for this study – a child growing up in a generally poor, but peaceful environment – can be based on what is already known about these situations. Children in poor countries and poor areas of the world already face enormous risks. When conflict erupts, an already fragile existence can be made even more unstable. Malnutrition and diarrheal disease are complex conditions which can be brought on or exacerbated in many ways related to conflict from increased food insecurity if crops are burned, food prices rise, or caregivers are abducted or conscripted, to a case of dysentery going untreated because health care facilities have shut down, there are no proper medications, or the family must put their dwindling resources elsewhere. Thus, this research does not purport that conflict is the only challenge for young children in the developing world, but it illustrates quantitatively that exposing them to armed conflict increases the risk of morbidity and potentially, mortality. Causal linkages between conflict and malnutrition/diarrhea should be viewed with caution due to likely unidentified confounding, but further research is merited to help safeguard the health of children in extreme circumstances.

The prevention and treatment of illness and injury in children is a fundamental responsibility for those engaged in humanitarian activities, whether they are government entities, insurgents, or local and international aid agencies.[64] The results of this study underscore the importance of maternal and child health interventions to reduce morbidity and excess mortality in conflict zones. Each situation is unique and care must be taken to avoid inadvertently causing harm (for example, if providing food makes people targets of violent attacks), but activities that address malnutrition and diarrheal disease generally include:

- Prioritizing pregnant and breastfeeding women for interventions aimed at providing food, cash or voucher transfers, or other types of nutritional support.
- Providing pregnant and breastfeeding women with micronutrient supplementation such as folic acid and iron.

- Encouraging the early initiation of exclusive breastfeeding, exclusive breastfeeding for 6 months, continued breastfeeding for 24 months or beyond, and the introduction of adequate and safe complementary food at 6 months.
- Ensuring nutritional and health support for especially vulnerable children such as orphans.
- Managing moderate malnutrition, often with supplementary food rations.
- Managing severe malnutrition with the treatment of co-morbidities as necessary.
- Controlling communicable diseases such as diarrhea (with oral rehydration therapy, zinc), acute respiratory infections, and vaccine-preventable diseases including measles.
- Providing safe water, appropriate sanitation facilities, adequate shelter, cooking utensils, soap for handwashing, etc.
- Addressing long-term issues of food insecurity (such as by supporting primary food production), unemployment, poverty, and weak governance.[64]

4.6 Appendix

This Appendix contains the results of analyses conducted for height-for-age and moderate/severe stunting. As mentioned in the Discussion section, the results are statistically significant, but not valid in this analysis as the trend cannot be attributed to the Boko Haram conflict.

Chapter 5. Conclusions

The goal of this dissertation was to contribute to our understanding of how climate and conflict impacts diarrheal disease and malnutrition among young children. The research in Chapters 2 and 3 examined the associations between climate and diarrheal disease across the whole study area – ten countries in West Africa during the period 2008-2013 – using geo-spatial methodologies. The study in Chapter 4 took a closer look at one particular area – Northeast Nigeria – to examine the effects of the on-going conflict there on childhood diarrhea and malnutrition with a double-difference methodology.

5.1 Major findings from Chapter 2

1. Regression analysis shows that household and climatic variables influence the odds of diarrhea in children in West Africa.

Results from a single model with odds ratios (95% confidence intervals):

- Moderate rainfall of 0.01 to 10 mm compared to no rainfall: 0.80 (0.72-0.89)
- Heavier rainfall of greater than 40 mm compared to no rainfall: 1.20 (1.08-1.33)
- Hotter temperatures (up to 34□C) compared to cooler ones (less than 25□C): 1.30 (1.11-1.52)
- Poorest quintile compared to richest: 1.51 (1.34-1.69)
- Desert climate zone compared to fully humid/monsoonal: 1.57 (1.22-2.02)
- Urban areas compared to rural: 1.82 (1.53-2.16)
- Households with 22 people or more compared to households with 2-6 people: 1.89 (1.6-2.2)
- Mothers with only a primary education compared to those with post-secondary education: 2.13 (1.73-2.61)
- Children aged 12-23 months compared to children aged 24-59 months: 2.38 (2.27-2.51)

The odds of diarrhea among children were increased and significant with increased poverty, household size, among children whose mothers had little education, and among toddlers age 12 to 23 months. The mother's

education and child's age had the highest effect. This indicates the importance of resources and knowledge to combat diarrheal disease; for example that a family knows the importance of clean water, can afford it, and ensures the youngest members of the household are prioritized for its use. In this analysis, children in urban areas are on average more at risk than their rural counterparts, which indicates that there is an urban disadvantage in this part of Africa. Odds of diarrhea were increased and significant as climate zones grew progressively drier, *ceteris paribus*, which speaks to the presence of other unobserved factors such as food security, in the harsh Sahelian climate. Diarrhea odds increased with increasing temperatures, perhaps a result of pathogen survival and replication. Children in environments where there was moderate rainfall had lower odds of diarrhea than those in both very dry areas and very wet areas, demonstrating how diarrhea pathogens can become concentrated with low rainfall, and can spread through water and sanitation systems with high rainfall.

2. Even after adjusting for household and climatic covariates, geo-spatial analysis shows there are 23 statistically significant clusters of elevated risk of diarrheal disease throughout the study area. Increased risk was greatest in certain urban areas (7.16 in Cotonou, Benin; 7.21 in Kaduna, Nigeria), but substantial throughout the study area (over 2 in 18 out of 23 clusters). Some clusters encompassed whole cities – Dakar, Senegal had a relative risk of 4.79 and Yaoundé, Cameroon had a relative risk of 2.14. Other clusters were more mixed, for example, the city of Bamako, Mali and the surrounding rangelands had a relative risk of 5.09. Other clusters were small villages (one in southern central Nigeria had a relative risk of 6.03) and still others were in areas with very sparse populations (northern Burkina Faso, relative risk 2.22; western central Cameroon, relative risk 3.69). These findings indicate that a) there are unobserved factors which influence diarrhea risk – perhaps food security or failed municipal systems and b) risk cannot be characterized by designations such as urban or rural in themselves.

3. These findings largely agree with the original hypotheses in that they underscore the importance of household and climatic factors when determining risk factor for diarrheal disease and that the risk is not uniform across or within nations. The effect of temperature was stronger than anticipated, which may be a result specific to the tropics. Additionally, there were more clusters of elevated risk in urban areas than were expected, which speaks to the question of urban advantage and disadvantage in sub-Saharan Africa.

4. The study provides further evidence of the importance of development programs such as education in reducing the risk of childhood diarrhea. It also gives insight into areas of particular risk which could be targeted for development and adaptation interventions. These interventions could be tailored to the context; for example improved municipal water and sewage systems in cities such as Dakar and Yaoundé and food security adaptation in rural areas such as southern Mali.

5.2 Major findings from Chapter 3

1. Geospatial analysis of childhood diarrheal disease and socioeconomic, environmental and climatic explanatory factors in West Africa show that a) there are spatially varying relationships among the associations (non-stationarity), b) the associations are both positive and negative depending on location, and c) the statistical significance of these associations is also dependent on place.

2. The geospatial analysis revealed complex relationships that were masked by the global model, which produces one average value for each coefficient. For example, the percent of the population with an unimproved water source was not statistically significant in the global model, but showed an increased risk of up to 11% in locations such as Freetown, Sierra Leone; Conakry, Guinea; and Lagos, Nigeria in the Geographically Weighted Poisson Regression model.

Range of relative risk in a single GWPR model:

- Population with unimproved water source (per 10% increase): 0.93 – 1.11
- Population with unimproved toilet type (per 10% increase): 0.84 – 1.10
- Mothers with no formal education (per 10% increase): 0.78 – 1.14
- Latitude (per 1-degree increase): 0.02 – 15.06
- Temperature (per 1-degree increase): 0.28 – 1.83
- Rainfall (per 10-mm increase): 0.43 – 41.30
- Altitude (per 100-m increase): 0.33 – 2.80
- Population density (per 100-pp/km2 increase): 0.65 – 1.68

3. The complexity of these relationships was not anticipated in the original hypothesis. The degree of spatial non-stationarity shows that even within a single model, factors affecting the risk of diarrheal disease are not statistically significant in many areas and very strong in others. The positive and negative associations are reasonable for environmental and climatic factors, but more difficult to interpret for socio-economic ones (e.g., decreased risk when a large proportion of the community uses drinking water that has a high probability of being contaminated).

4. This analysis is best seen as an exploration of regional dynamics affecting diarrheal disease. However, it does point to certain areas which face particular risk factors such as in certain urban centers, low-elevation areas (coastal and along rivers), remote areas such as western Mali, conflict zones (northeast Nigeria), and special populations such as the Dogon who live along the Bangiagara Escarpment. With further analysis, interventions to combat specific risk factors may be developed.

5.3 Major findings from Chapter 4

1. Results from the double-difference analysis suggest that if children exposed to the conflict in Northeast Nigeria had not been exposed, their average weight-for-height z-scores would be 0.49 standard deviations higher ($p < 0.001$) than they are. This would bring the average from -0.74 to -0.25 (from a "serious" nutritional crisis to a "poor" one).

2. Additionally, the prevalence of moderate or severe wasting would be 13 percentage points lower (mean z-statistic -4.2) than it is, bringing down the proportion from 23% (a "critical" nutritional crisis) to 10% (a "serious" nutritional crisis and close to the average for West Africa, 9%).

3. The prevalence of diarrhea would also be lower by 8 percentage points (mean z-statistic -3.3), which would bring the rates down from 20% in the conflict states to 12% (close to the Nigerian average of 10%).

4. These findings support the original hypothesis, although there were greater differences in baseline outcomes for conflict and non-conflict states than anticipated. Also, a linear downward trend was expected, at least in the baseline period, but the trends were more erratic, likely due to few time periods for comparison. As hypothesized, significant improvements were found for the counterfactual scenario (if children exposed to conflict had not been exposed) for weight-for-height, moderate/severe wasting, and diarrhea. Weight-for-age and moderate/severe underweight did not have statistically significant doubledifference estimates and height-for age and moderate/severe stunting did not meet the common trends assumption.

5. This analysis speaks to the importance of ensuring children and their mothers receive adequate health and nutritional support in the "first 1,000 days" – from conception to age two (and beyond), especially in extraordinary circumstances such as when a community is faced with armed conflict. Development projects

such as poverty reduction are important, but conflict areas will likely require additional assistance to ensure access to goods and services such as food and specialized health care.

5.4 Significance of findings

The findings of the studies in this dissertation contribute to our understanding of how climate and conflict affect child health. Previous studies have given varied results on specific climatic factors. Here, the associations in aspatial regression analyses are quite clear, while geospatial methods indicate the complexity of factors such as overall climate, rainfall, and temperature. The effects of conflict on child health are conceptually inherent and have been quantified with different methods and outcomes. The research here furthers those efforts by quantifying the impact of a particular conflict on the health and growth of young children.

The findings from this research support on-going development goals which aim to improve modifiable factors including increased coverage of improved water sources and sanitation facilities, increased educational attainment, the alleviation of poverty and food insecurity, and resolving on-going conflicts around the world. The results also support adaptation measures, which are aimed at factors that are difficult to change in themselves, such as living in areas where temperatures are increasing or rainfall is decreasing. Such measures include promoting income diversification and access to goods and services for farmers and pastoralists and improving infrastructure and public services in urban areas.

5.5 Limitations

The studies in this dissertation have several overlapping limitations. First, the studies in Chapters 2 and 3 are cross-sectional and intentionally descriptive. Thus, while they provide insight into various associations, they do not imply causality. The quasi-experimental double-difference analysis in Chapter 4 can be used to make

limited causal inferences; for example, the outcomes are different for children exposed to conflict or not, but we do not know by what mechanism or mechanisms (e.g., increased food insecurity, disrupted health services, population displacement, etc.).

Second is the issue of temporality when using survey data. The DHS surveys are an enormous undertaking and most participating countries only do them every few years (although a few, including Senegal, have committed to continuous surveys). For this reason, although they are treated as cross-sectional studies, Chapters 2 and 3 contain data which span five years. West Africa is a rapidly changing sub-region with some positive developments such as overall decreasing rates of child mortality and some negative trends such as growing inequality. Thus, while these changes are generally slow, it is difficult to obtain a true cross-sectional snapshot of several countries at once which could introduce bias into the estimates. The timing of the surveys may capture real-time events, such as the declaration of the state of emergency in Northeast Nigeria. The DHS program gives no indication that their survey methodology was hampered by these particular events – still, if teams avoided the most affected areas or were rushed in their interviews, rates of malnutrition or other diseases could be underestimated. Similarly, there were temporal constraints for the common trends analysis in Chapter 4: more timepoints may have shown clearer trends, especially for stunting. On a smaller timescale is how households are interviewed over the course of the survey. Ideally, sub-national regions would be surveyed simultaneously, which would allow for more comparable analysis with regards to rapidly changing climatic factors such as rainfall. There are also temporal issues inherent in surveys about episodic diseases such as diarrhea in that there is a 2-week recall period which could introduce bias.

Third are spatial constraints, especially for Chapters 2 and 3. The sampling points are intentionally offset and are broad estimates of the location of the population of interest. The use of Voronoi polygons as pseudocatchment areas in Chapter 2 made visualization easier, but may be misleading, especially in areas

where sampling points were far apart. Additionally, other covariates such as rainfall, temperature, altitude, urban limits and so on are at different spatial resolutions, which introduce different biases when applied to sampling points. For example, the SRTM data for altitude are very high resolution (< 100 meters), so relatively accurate while temperature rasters are lower resolution (0.5x0.5 degrees, which is approximately 55 kilometers at the equator) and therefore a coarser estimate of the true measure.

Fourth are various methodological issues such as the bias introduced when the number of observations per sampling point varies greatly, even after weighting. This could be due to missing data for key variables, but is also the result of the DHS sampling method, which focuses on women of reproductive age rather than children under five. Another issue is multicollinearity across local estimates in Geographically Weighted Regression (Chapter 3). If there are parameter redundancies, a single coefficient cannot be interpreted independently of the other coefficients at the same location, which can result in misleading findings. Another example of methodological issues is finding an appropriate comparison group in double-difference analysis (Chapter 4). For a study on conflict, the ideal comparison group would be exactly the same as the intervention group, except for conflict to exposure. In this study, the other states of the Northeast Zone were chosen as the comparison group since the population is closest in terms of climate, livelihoods, culture, and governance and also because the survey interviews were conducted within the same timeframe as the conflict areas. However, the non-conflict states were subjected to attacks from Boko Haram, although to a lesser degree. In these situations, the analysis is often conducted again with a different comparison group to validate the original results. In Nigeria, this could be the Northwest Zone, for example. Other limitations are addressed as areas for improvement in the section below.

5.6 Future research directions

There are numerous areas for future research in the fields of climate variability, conflict and child health. The types of geo-spatial analyses used in this research could be replicated, but using spatial regimes other than administrative boundaries such as country borders. For example, the Sahel region is a transition zone between the fertile south and desert north stretching from Senegal and Mauritania in the west to Eritrea in the east, about 4,000 kilometers. While covering 10 countries, the population in this region – estimated to reach 100 million people by 2020 – are related by culture and livelihoods, which are largely determined by climate.[1] One area of research could be examining child health outcomes across the Sahel and determining whether certain coping mechanisms (crop diversification, mobile health teams that follow transhumant populations) improve outcomes and could be introduced to other Sahelian communities. The Sahel must also be studied in terms of climate change, its impact on child health, and what adaptation measures are most effective. Climate models are yet uncertain as to future rainfall patterns in the Sahel, but agree that the region will be one of the fastest warming areas in the world.[2] One impact from increasing climate variability (e.g., erratic rainy seasons) that is already being seen is migration to northern cities such as Dakar, Bamako, and Ouagadougou. Given this dissertation's findings on urban health disadvantage for some cities, an area of research could be to examine how these Sahelian cities can better adapt for influxes of migrants, including adequate services such as health care and education, but also infrastructure important to child health including sanitation and water systems (which are also becoming more stressed in the warming Sahel). The impacts of climate change on child health could also be studied using projections of the Köppen-Geiger climate classification scheme, which are already available through the year 2100 (though likely will have to be updated as climate models improve).[3] An example of a study which could be conducted in one geographic zone with specific socio-economic measures is from the livelihood zones produced by the Famine Early Warning Network. For example, all along the coast of Nigeria, people fish from July to March and plant crops from March through November.[4] Thus wealth in the rural areas is largely determined by the type of fishing gear (canoes with outboard motors vs. nets and hooks) and the amount of land a household owns.[4] A

research project could examine the child health outcomes of these populations, again to determine which interventions (e.g., sustainable fishing co-operatives) may improve population health.

Conducting research on smaller spatial scales would also likely provide telling results. For example, also along the coast of Nigeria, is Lagos, by far the region's largest city. In the study in Chapter 2, Lagos was not an area of elevated risk even before controlling for household or climate variables, despite having extensive slums, including large neighborhoods on stilts within a coastal lagoon.[5] However, both altitude and percent of households with unimproved water sources did invoke increased risk in the GWR analysis (Chapter 3). A project investigating Lagos at high resolution may be able to determine with greater accuracy which risk factors are most important and at which specific locations. If contaminated water sources are a risk factor, it will be especially important to address the issue as the number of people in Lagos vulnerable to coastal flooding due to rising sea level is expected to reach more than 3 million by the year 2070.[6] This study would also contribute to the very small body of research which specifically examines low elevation coastal zones with regards to health outcomes. However, the intentional displacement of the DHS sampling points and the fact that the DHS household wealth index may not detect urban vulnerability (e.g., households with flush toilets, but living next to overflowing sewer systems), means that this analysis would likely have to be done with a different data set. Flooding is an example of an aspect of climate variability not addressed in this dissertation – extreme events. Flooding is often harmful, but is also a reliable irrigation technique which supports millions of people, for example in the Inner Niger Delta in Mali. The effects of proximity to flood zones on child health could be studied and future predictions made with assumptions about climate change, population changes, and resource management.

Given the correct data structure, research could also be conducted using different temporal regimes. SaTScan software, used in Chapter 2, is capable of conducting spatiotemporal cluster analysis, but with most survey

data, temporal clusters would just be where the interviews were being conducted. However, if survey teams were in several areas at once or for example, health facility records for a particular month were being compared, this would provide insight into the contribution of factors such as rainfall or even conflict. GWR analysis, used in Chapter 3, could also be conducted over time; for example an analysis of risk factors during the rainy season and then with the same population in the dry season.

There are other conflict zones for which there is little quantitative analysis available and where the methods used in Chapter 4 could be replicated. For double-difference analysis, a clear before-after time demarcation as well as a reasonable comparison group is needed. Therefore, the conflict in northern Mali may not be appropriate as there has been unrest in the region for decades. However, research could conceivably be done on a smaller spatial scale; for example, a comparison of violent and non-violent causes of death in the city of Timbuktu before and after the ten month occupation by Islamist militants in 2012-2013. Another question of interest brings together the two main drivers of this dissertation: does climate variability contribute to conflict and will climate change exacerbate conflict?

The data sources and methodologies used in this dissertation are continuously growing and improving. There are many more climate datasets than even a few years ago and geospatial software developers continue to add in new features. The DHS datasets are an invaluable resource; however, with growing recognition of how climate affects not only health, but other demographic phenomena such as migration, it would be beneficial if the DHS program could review how interviews are scheduled within sub-national regions in order to better capture climate variables. Likewise, questions about migration should be incorporated into as many surveys as possible, not only to address issues such as urbanization, but also displacement due to conflict. The problems of the developing world can no longer be considered completely separate from those of the developed world. For example, the nutrition transition to the “Western diet” is uneven between and within

poor countries which is leading to simultaneous undernutrition and overnutrition. Thus, DHS should consider including the assessment of nutritional edema into their surveys to avoid misclassification bias and more importantly, to identify severely malnourished children with the condition. The technique is simple and fast - simply pressing ones thumbs into a child's feet for 3 seconds and noting if the indentation remains. Another consideration for DHS is the use of mid-upper arm circumference (MUAC) instead of or in addition to weightfor-height. MUAC is easier to measure than weight-for-height (height, especially is subject to inter-operator bias), and does not require additional charts or software to calculate usable numbers (which increases the possibility of error).[7] MUAC is less trying on very sick children and can be routinely done by trained personnel in resource-poor settings as the tool (a modified tape measure) is quite inexpensive.[7]

One of the particular issues software developers could address is the use of categorical variables in Geographically Weighted Regression programs. For example, in West Africa, the climate classes do not exactly follow latitude, and more interpretable results may be obtained with these well-defined spatial regimes. Additionally, there is a fundamental difference between a household with an unimproved toilet type and the percentage of households within a "community" (the approximately 20 households within a DHS sampling point) with unimproved toilet types. In some cases, the latter may be more relevant, but the researcher would benefit from having the ability to choose between individual-level or community-level characteristics (or both). Another software improvement would be for mapping relative risk as shown in Chapter 3. Current Esri software does not allow the user to choose a particular point (for relative risk, 1) and then choose two different color schemes with gradients to indicate increasing risk in one direction and decreasing risk in the other. For this study, two layers were created for each direction away from 1 and separate gradients created in the legend. The legends were then converted to graphics and manually rescaled to approximate the range of risk overall (for example, for a range of 0.50 to 2, the decreased risk scale should be one quarter the size of the increased risk scale) and then joined at the 1 mark. While this is an improvement over previous methods,

it is still somewhat inaccurate and could doubtless be automated. The advent of geocoded data and geospatial methods has opened new areas of study within public health and other fields. Continuous improvements to both data and methods will increase our understanding of complex relationships even more.

Abstract

Risk factors and costs influencing hospitalizations due to heat-related illnesses: patterns of hospitalization by

Adviser: Professor Grace Sembajwe

The objective of this dissertation was to identify individual and environmental risk factors, investigate outcomes and hospital resource use, including costs, and document the pattern of heat-related illness hospitalizations in the United States. The main data source for the study population was the 2001-2010 Nationwide Inpatient Sample (NIS). The study population for heat-related illnesses (HRIs) consists of patients in the NIS with at least one diagnosis of a heatrelated illness (ICD-9 codes 992.0 – 992.9) from 2001 to 2010. Outcome analysis included a study population of patients who had primary or secondary diagnoses of diabetes, cardiovascular diseases, respiratory illnesses, nephritic illnesses and acute renal failure along with a diagnosis of a heat-related illness. Outcomes for costs were calculated and adjusted using the medical consumer price index for 2013. Data on air conditioner use and total cost of electricity use from air conditioning was derived from the Residential Energy Consumption Survey. This study identified a number of previously unknown risk factors for heat morbidity HRI, including age greater than 40, males and hospitalization in rural areas and small urban clusters. Additionally, stratified analyses of outcomes further identified specific risk factors among vulnerable populations. Elevated risk of negative health outcomes and increased hospital resource use was seen in patients diagnosed with common comorbidities, in particular those of a lower socioeconomic status, minority and most age groups with diagnoses of cardiac and respiratory diseases with a HRI. Analyses of costs showed substantial costs associated with hospitalizations due to heat-related illnesses with the average mean cost approximately $52.7 million while the

total aggregate cost for the time period at just over half a billion dollars. Projected estimates for the average yearly cost of these hospitalizations in the future climate with estimates around half a billion US dollars by the late-21st century.

In conclusion, the study revealed a number of risk factors and negative health outcomes associated with hospitalizations of heat-related illnesses. These findings provide additional scientific evidence that heat-related illnesses will continue to rise and will continue to be a public health burden as climate changes increase in frequency and intensity of extreme weather events.

Acknowledgements

I want to deeply thank the members of my dissertation committee – Grace Sembajwe, Jean Grassman, Peter Marcotullio, David Himmelstein and Steffie Woolhandler – your support, guidance and expert knowledge helped me tremendously along the way and I am forever grateful. I want to especially thank Jean (chairperson) and Grace (sponsor). Jean, you were with me from day one and your unwavering support helped me navigate through this whole process successfully, thank you so much. Grace, it was perfect timing when you came to CUNY as a new faculty member and agreed to be my sponsor. Your enthusiasm, knowledge and commitment to my work buoyed me on many occasions and your excitement for my research always gave me hope that I can do this. And I did it - you are a great mentor and I cannot thank you enough.

I also want to thank the professors of the Environmental and Occupational Health track, your encouragement for me, as the first EOH DPH graduate was always inspiring and supportive. I want to thank the faculty at the CUNY SPH and those I worked with specifically, Heidi Jones, Bill Gallo, Frank Mirer, Jack Caravanos, Mimi Fahs, Susan Klitzman and Trudy Lieberman. The administration of the CUNY SPH and the DPH program have always been supportive as well and helped in guiding me through the program. Thank you to the founding Dean Kenneth Olden and Dean Ayman El-Mohandes and executive officers Nick Freudenberg and Denis Nash, your personal and financial support from the school enabled me to complete the program. The administrative staff was also a big help in getting me though the program. I want to especially thank Jason Pavo and Sara Ingram. Day in and day out you answered questions, sometimes the same exact ones I asked a week prior, directed me through the bureaucracy and always listened. You gave me my (rightfully so) 15 minutes of fame in the DPH newsletter and were supportive and many ways. I will miss being in the office with both of you.

It was my fellow classmates who truly understood what we were going through. We all supported and encouraged each other and I will miss that comradery and creative environment. An ‘epidemiological’ thanks to NAMES REDACTED – this was my weakest area and you put up with my constant questions about analyses and SAS – you’re angels. My writing group – NAMES REDACTED – what can I say, you were the most supportive in my life during this time and we accomplished a lot together. I could not have done any of this without you. I know you will always be a part of my life and I wouldn’t want it any other way. A great thanks to my cartographer, geographer and murder mystery friend, NAMES REDACTED, your guidance in spatial analysis helped me through a tough spot in my research.

Finally to my close friends and family – you may not have understood why I was in school for so long, but you were always there for me no matter what. I can never thank you enough, but know that it has always meant the most to me that you continued to support me in any way you could and were always proud of me. I love you all dearly.

Chapter 1. Introduction

1.1. Climate change and extreme weather events

Global warming and climate change have increased the frequency and severity of weatherrelated hazards. This trend has prompted governments to research ways to adapt to our changing climate in order to reduce morbidity and mortality during extreme weather events. Studies by climate change researchers[1,2] indicate that the frequency and intensity of extreme climate events has increased in recent decades, and that adaptation to these rapid changes is more challenging than gradual climate change. Moreover, extreme climate events disproportionately affect vulnerable populations who experience higher exposure (e.g., low-income populations facing extreme heat often lack access to air conditioning and are more likely than the affluent to live in flood-prone areas) or higher susceptibility (e.g., elderly individuals are more physiologically vulnerable to heat-related illness) to such events.[3] Heat waves are one such extreme weather phenomena that have increased in frequency and are likely to have dire consequences for vulnerable populations. Recent studies indicate that as global temperatures continue to rise due to the increase of greenhouse gases the frequency and intensity of extreme heat events are likely to increase.[4-7] Climate modeling also predicts that heat waves are likely to affect areas that had not previously experienced extreme heat events, increasing the geographic range and populations at risk of heat waves.[7] This increase in geographic areas prone to heat waves will in turn increase the incidence of heat-related illness and other public health impacts. Although, on average, there were only about 400 deaths were directly attributed to heat in the United States in 2002[8] an increase in ambient temperature can also exacerbate underlying chronic conditions such as cardiovascular,

respiratory, and cerebrovascular diseases as well as psychiatric conditions.[9-11] Air pollution also increases during extreme heat events and may further exacerbating underlying medical conditions, particularly respiratory diseases.[11,12] Studies have found a 5-11% increase in hospital admissions as well as increased use of ambulances, telephone helplines and dispatches by fire departments during heat waves.[13,14] Hence, the expected increase in heat-related and exacerbated illness is likely to stress health care systems and emergency responders.

Although public health interventions may focus on the prevention of heat-related illness, public health practitioners and policymakers should also direct preventive measures to the community- and environment-level effects of extreme heat events.[15,16] Heat waves can have devastating effects on livestock and crops, and can damage electrical equipment, roads, bridges and other types of infrastructure.[16] In countries like Australia and western parts of the United States heat waves are often accompanied by brush and forest fires, which further stress limited emergency responder resources.[16] Heat waves also strain energy resources as many people use their air conditioners in an effort to combat the heat. This increase in use of air conditioners may stress power plants and electrical transfer stations, and in some cases, result in blackouts and brownouts. In 2004, 30% of California's peak electricity demand was due to air conditioning use alone and has been projected to increase annually.[17] Air conditioners also emit heat, increasing ambient temperatures as well as air pollutants due to the increased demand for electricity which is mainly produced by fossil fuel-burning power plants.[18,19]

Climate change, including increasing temperatures and related changes in other aspects of global climate change is likely to initiate a number of other harmful effects on public health. Principle concerns include contamination of water and food; changes in infectious disease transmission rates; increased allergen production; changes in populations due to loss of habitat and sea level

rise; and nutritional shortages from disruptions in food production and transportation systems.[20] Rising temperature will likely increase the spread and transmission rate of some infectious diseases that proliferate at higher temperatures like cholera and salmonella. Vector-borne and rodent-borne disease rates are also likely to increase due to increased temperatures that allow for longer breeding times and the spread of the transmissible agent to higher latitudes.[21,22] In addition to the spread of vector-borne and rodent-borne disease to new areas, the distribution of plant species and pollen production is likely to undergo change triggering changes in the incidence of allergic symptoms. Increased temperatures may change the amount of time humans spend outdoors, also increasing their chance of exposure to allergens and allergic reactions.[11] Increased temperatures may indirectly affect population growth through the reduced availability of water and food sources, increasing economic disparities and migration to urban centers. Migration to urban areas may further increase heat-related illnesses as population growth puts additional stress on already weak health systems. Civil strife and wars due to lack of resources may also force populations to migrate to already congested locations. These changes, as well as the public health disparities listed above, will have the greatest impact on those who are already socially and economically disadvantaged.[21]

Climate change will exacerbate existing food insecurities in many locations. A recent study found that, in the US for every degree rise in temperature corn and soya bean yields fell by 17%.[23] Rising temperatures will take a toll on farmer's crops adding to food shortages in already food scarce locations like sub-Saharan Africa and south Asia. Increased temperatures are also likely to result in prolonged droughts and/or flooding destroying crops and interrupting the growing season at critical junctures.[22,23]

Although a rise in global temperatures will have a devastating effect in many public health arenas, the most thoroughly studied climate-health impact in developed countries are the acute

effects of extreme heat events. Despite numerous studies there are gaps in knowledge surrounding population-level public health impacts of heat events, vulnerable populations, and effective public health protection strategies. For example, heat health warning systems (HHWS) have been implemented in a number of developed cities such as London, Chicago and Madrid though the protective capacity of these systems are reduced because of limited information regarding how the system should be triggered and concerns over the most effective messaging for vulnerable populations.[24] Researchers have also indicated that poor and developing countries will suffer the worst effects due to a global rise in temperatures and ensuing heat events, though most of this data comes from predictions based on climate modeling and current socioeconomic conditions.[21]

1.2. Heat-related illness

Excessive hot weather can induce illness and even death in humans.[25] As climate change increases the frequency and intensity of extreme heat events scientists and health officials should work towards improving our understanding of the causes for heat-related illnesses (HRIs). To fully understand HRIs initiated by extreme heat events we must first settle on a definition of a heat wave and a HRI. The definition of a heat wave varies by location, as risk is strongly dependent on climate and adaptation. For example, people living in colder climates are more adapted to cold weather while those living in hotter climates are more adapted to hot weather. In addition, improved infrastructure including better housing, availability of air conditioning and access to health care improves an individual's ability to adapt to hot weather.

To arrive at a definition of a heat wave, we must first determine the threshold temperature which would be considered above normal and which may induce negative health effects. Maximum

daytime temperature, minimum nighttime temperature and mean temperature are commonly used measures of heat exposure. Factors such as wind speed, humidity and barometric pressure are also used by some researchers in addition to temperature indices. Apparent temperature (AT) or heat index is one measure often used. This calculated temperature is an adjustment of the ambient temperature based on humidity and wind speed.[26]

Apparent temperature combined with weather patterns and duration of heat delineates when and where a heat wave occurs. For example, the United States defines a heat wave as two or more days of excessively hot weather in which the thresholds of daytime high and nighttime low heat indexes are exceeded (105°F and 80°F respectively).[27] Although a majority of studies take the approach of using AT (and defining a threshold) as an indicator for heat related morbidity and mortality, Barnett, et al. (2010) point out that there is no universally accepted measure of temperature that is used across heat morbidity and mortality studies.[28] This lack of a standardized definition is a significant disadvantage in comparative analysis among studies.

Heat-related illnesses are usually termed heat stroke, heat exhaustion and heat stress. Each is a variation of symptoms from physiological strain due to exposure to heat. Heat stress is defined as perceived discomfort and physiological strain associated with exposure to a hot environment. Heat exhaustion is a mild-to-moderate illness due to water or salt depletion. Heat stroke is a severe illness characterized by a core body temperature of >40.6°C.[29]

Heat stroke and resulting multi-organ failure is due to a complex interplay between the "acute physiological alterations associated with hyperthermia, the direct cytotoxicity of heat, and the inflammatory and coagulation responses of the host".[29,30] Until 1995, there was little consensus on the criteria that defined a HRI or heat-related death. The increasing frequency of heat waves, and particularly the 1995 heat wave in Chicago, caused medical examiners to take a closer look at

the definition of a heat-related death. The criteria for diagnosing a heat-related illness remained largely unchanged based on patient symptoms. However, because of the number of people who died as a result of the 1995 Chicago heat wave, many of which were found hours or days after they died, a broader definition of a heat-related death was needed, outside of having a core body temperature of >40.6°C.

The new definition now considers deaths from heat waves that are attributed not only to an elevated core body temperature but also if exposure to high ambient heat either caused the death or significantly contributed to it by considering factors concerning the environment at the time the body was found based on the history of high ambient temperature and the exclusion of other causes of heat stroke.[31,32]

A recent meta-analysis indicated a number of prognostic factors for heat-related deaths: Living alone, unable to care for one-self, being confined to a bed and those that do not leave home were among the greatest prognostic factors for heat-related deaths.[29] A study analyzing prognostic factors from the 2003 heat wave in France found that in addition to the above listed factors, living in an institution and transportation time to a medical facility contributed significantly to whether an individual had a negative outcome after suffering from a heat-related illness.[33]

Post-mortem studies of heat-related deaths provide insight into risk factors to heat-related illness. Studies from the 1995 Chicago heat wave and the 2006 California heat wave have shown that individuals with a history of cardiovascular, cerebrovascular, respiratory, psychiatric or renal disorders and those with diabetes or secondary infections are at increased risk of heat-related illness. For example during the 1995 Chicago heat wave there were increased hospital admissions with excess inpatient admissions for cardiovascular (31%), respiratory (20%) and renal diseases (23%) and diabetes (30%).[34] In many cases a condition such as kidney disease is

exacerbated by increased ambient temperatures forcing people to seek medical care. The prevalence of many of these underlying conditions increases with age which is the strongest risk factor for a HRI. The elderly, particularly those with an underlying medical condition, have impaired thermoregulation preventing normal body mechanisms from cooling them effectively. Moreover, medications that are commonly prescribed to the elderly such as diuretics increase this risk.[34,35]

A person's environment can play a significant role in susceptibility to HRIs. The urban heat island (UHI) effect exacerbates the risk of a HRI posed by the increase of thermal stress from the environment.[36] An UHI is characterized by increased temperatures in urban areas due to heat being retained by concrete and asphalt. This heat is then released back into the environment, particularly at night, depriving the urban environment of time to cool.[37] Living on the top floor of an apartment building also increases susceptibility to HRIs, as do forms of social isolation such as not leaving the home daily and living alone.[38]

Race and socioeconomic status also affect the risk of HRI. Minorities and the economically disadvantaged have an increased risk to heat-related illness due to factors such as lack of air conditioning, lower educational attainment and language barriers which may limit their ability to understand heat wave warning messages. A recent study in four US cities found air conditioner prevalence in White households was more than double that in Black households. This same study indicated that heat associated mortality was more than twice as high among Blacks as Whites.[39] Once an individual starts suffering from heat stroke, how promptly body temperature is reduced to normal levels is a major determinant of the eventual outcome. Studies of the aftermath of the devastating 2003 heat wave in Europe found that 50-60% of patients admitted to the hospital for heat stroke died as a result. Once multi-organ failure starts it is difficult to reverse.[40] Even

patients who survive an initial episode of heat stroke often succumb in the ensuing months. In the two studies from the 2003 heat wave in Europe and one from the 1995 Chicago heat wave, patients who were admitted, diagnosed with heat stroke and then discharged from the hospital had survival rate of 20-50% at 3 months.[40,41] A decreased chance of survival was associated with the level of disability after discharge. A study from Australia also found that approximately 20% of heat stroke patients were discharged to a rehabilitation facility or nursing home because they could no longer live independently. This Australian study along with one from the 2003 heat wave in France found that the length of hospitalization generally ranged from 3 to 10 days, with occasional longer stays when heat stroke was complicated by other medical conditions.[42,43] The increased number of hospitalizations during heat waves, and the lengthy hospital stays associated with these events, raises the question of how much HRIs are costing both affected individuals and society at large. The cost of prevention may be less expensive than the high cost of hospitalization without preventative measures. However, few cost and benefit analyses for preventive systems like heat health warning systems have been implemented to explore this issue.[44] Bassil, et al. emphasize that the cost of heat illness prevention strategies such as educational material and cooling centers are relatively low compared to the high cost of hospitalization.[15]

Challenges in identifying health impact data and lack of consensus on health care cost validation methods has made it difficult to establish a well-accepted structure for quantifying the costs of human health effects to climate change. A study of cost effectiveness for heat events in Europe estimated that in the city of Rome inaction on the prevention of HRIs could cost €283 million ($388 million USD) annually by the year 2020.[45] Hospitalizations for HRI in Germany using various climate scenarios result in hospitalization costs predicted to be approximately €300 to

700 million ($400 to 930 million USD) annually by the latter part of the 21st century, six times higher than hospitalization costs today.[46,47]

Information concerning the prognostic or risk factors of HRIs and the outcomes and costs associated with heat-related illnesses and deaths has been reviewed though it is apparent additional research is still needed in these areas. Economic assessments of the costs associated with the health impacts due to heat events are limited and lacking in past research studies. Improving the standardization of calculations for cost estimates and capturing comprehensive health data will help to quantify human health effects and costs for heat events. Also, as the number of heat events increases it is important to improve predictive modeling to forecast extreme heat events. Collaboration between disciplines, including climatologists, geographers, social scientists and public health researchers is needed to describe the many variables that go into predictive modeling and to remove uncertainties and improve accuracy.

1.3. Vulnerable populations to extreme heat events

Many different definitions and conceptual frameworks for understanding vulnerability have been proposed. In 1993, Aday defined vulnerability as being "susceptible to harm or neglect, that is, acts of commission or omission on the part of others that can wound." Aday further explains that vulnerability is in part determined by the concepts of risks and exposure and there are certain key variables that play a role in predicting vulnerability and risk.[48]

The above definition of vulnerability can be applied to the topic of climate change and the hazards associated such as floods, coastal storms and heat waves. Blaikie defines vulnerability, in the context of natural hazard as "the characteristics of a person or group and their situation that influence their capacity to anticipate, cope with, resist and recover from the impact of a natural hazard".[49] Further the Intergovernmental Panel on Climate Change (IPCC) defines vulnerability

by how a system is susceptible to, or unable to cope with changes and adverse effects from climate variation and how this system is exposed to climatic hazards, its risk, and the ability to adapt to climate change.[50] This idea of adaptation to climate change was previously thought of as adapting our physical environment and infrastructure to prevent disaster, though the most recent IPCC report has noted that vulnerability is related to both social and environmental processes. The system then can be thought of as susceptibility and sensitivity towards an event and the ability to improve the (adaptive) capacity of a response to these identified vulnerabilities.[51]

Although I have highlighted a few definitions of vulnerability, there are many scholarly disciplines with different definitions and concepts of vulnerability. Social geography, economics, political science, ecology and the physical sciences all have contributed to the definition of vulnerability and also have different ideas of what it means to be vulnerable. Some definitions of vulnerability only examine causal mechanisms to identify vulnerable populations (e.g. drought) while others incorporate ideas of coping, mitigation and recovery. Another difference between definitions of vulnerability is the categorizations of exposures and risks used in these definitions. A few definitions look at a combination of exposure variables (environmental, social and geographical) while others may only incorporate economic or socioeconomic variables as metrics of risk to define vulnerability. For example, researchers are trying to identify populations vulnerable to coastal storms; a sociologist may identify poor populations as being the most vulnerable while a geographer may define vulnerable populations as only those who live along rivers or coasts. When studying the effects of climate change on vulnerable populations researchers need to reach consensus on the definition of vulnerable populations; inconsistent definitions or misunderstandings will hinder interpretation and application of research findings if these ideas are not established before a study begins.[52-54]

In addition to many definitions of vulnerability, several different conceptual frameworks guide how to assess who or what are vulnerable to extreme weather events. Some researchers adopt an approach similar to risk assessment methodology; identifying the exposure; the amount a person has been exposed to a hazard (dose); and how to mitigate the response.[55] Others have developed a framework which incorporates ideas from both risk assessment and vulnerability assessment. Vulnerability assessment conceptualizes the definition of vulnerability by developing robust and credible measures on factors that mediate vulnerability. These measures can then be used to establish a fundamental framework for assessment. A number of frameworks to describe vulnerability have been developed, each slightly different, but largely follow four fundamental dimensions: defining the system or population; defining key variables of risk and exposure (i.e. age, location, housing); defining the hazard and degree to which the system has been exposed; and establishing a temporal reference.[49,53,56,57] In addition to the above fundamental framework researchers also include aspects of mitigation and adaptation to their framework as well as defining inherent 'resiliencies' of populations to natural disasters and extreme weather events.[57,58]

Within the vulnerability assessment framework some researchers have also adopted a taxonomic approach to classifying who is vulnerable to extreme weather events. Common indicators are age, gender, occupation, education level, ethnicity, type of housing, and socio-economic status. Although there are advantages to using a quantitative metric to identify vulnerable populations, these indices are not universal and may vary from study to study. Two quantitative studies assessing vulnerability to heat mortality both included measures of race and age, but air conditioner ownership and prevalence of pre-existing medical conditions were only collected in one study.[39,59] Picking and choosing a variable based on what data is available to the researcher is sometimes unavoidable, though a standardized list of 'vulnerability measures' would help

comparative analyses between studies of heat-related morbidity and mortality and help to ascertain the strongest predictors of vulnerability.

However, some researchers suggest moving away from the quantitative approach and using qualitative methods to better understand the processes that contribute to vulnerability to climate change including underlying psychological factors and perceptions of vulnerability. Perceptions of vulnerability to anticipated heat events and derived experiences from these events are not easily measured. Each individual will have different perceptions and experiences of these events based on their own risk and level of exposure.[57,60] One approach, taken by Klinenberg in his 'social autopsy' of the 1995 Chicago heat wave was to use qualitative methods, through in-depth interviews, in discerning who and why individuals died as a result of the 1995 Chicago heat wave. Klinenberg found that both environmental and societal factors played major roles in determining who was vulnerable to this disaster. The elderly who were both poor and a racial/ethnic minority had the highest mortality because of social isolation, living alone, and not leaving home daily due to age and fear of the high crime rates in their neighborhoods.[61]

Additional research using qualitative methods, such as face-to-face interviewing as well as focus groups can help identify vulnerable sub-populations that could be missed when doing only quantitative analyses of heat morbidity and mortality. Integrated quantitative and qualitative data on social vulnerability can be a methodological advancement in understanding and assessing vulnerable populations to extreme heat events.[62]

Researchers have also used retrospective cohort studies of mortality and hospitalizations during heat waves to identify who is vulnerable to extreme heat events. Risk factors identified include being elderly, a minority, having psychiatric conditions including depression (possibly due to medications that interfere with thermoregulation), having an underlying medical condition such

as cardiovascular, respiratory or cerebrovascular disease and diabetes.[63-65] There is conflicting evidence as to whether children are more vulnerable to heat events, some researchers suggest they are while others argue they are not more vulnerable.[64,66] In an analysis of heat related mortality in California, children under 5 and infants under 1 year of age suffered higher mortality with increasing temperature. Mortality increased approximately 5% for these populations, over other populations, though failed to achieve any statistical significance.[67]

Socioeconomic factors, such as poverty, poor housing conditions, lack of higher education, and insufficient health care access are also listed as underlying causes of vulnerability.[68]

Poverty cannot cause a natural disaster though a natural disaster can exacerbate poverty, and in many cases we see that wealth is no barrier to extreme weather events. Events such as Hurricane Katrina in 2005 in the US and the 2003 European heat waves show that, even wealthy countries experience disastrous climatic events though vulnerability and risk are unevenly distributed. However, wealth does impact the process of recovery and the resilience of a population. For example, Bangladesh and The Netherlands share similar susceptibility to sea level rise but The Netherlands has greater economic resources, technology and stronger infrastructure while Bangladesh lacks these resources and may not recovery as quickly or fully as The Netherlands.[69] The IPCC and other researchers, have noted that global warming, climate change, and the increase in frequency and intensity of extreme weather events will affect those who are already vulnerable to even small climatic changes, particularly those living in hardships in developing countries.[70] According to the International Federation of Red Cross and Red Crescent Societies (IFRC) 70% of natural disasters between 2004 and 2008 occurred in developing nations in Africa, the Pacific region, Asia and the Middle East.[71] There are already great inequities between developed and developing nations, in food safety, water sanitation and inadequate housing; with

the threat of climate change and extreme weather events these inequities are likely to increase. While extreme heat events can contribute to famine and drought in areas of population vulnerability, other extreme weather events like coastal storms are a major concern in vulnerability assessment to climate change. As the world population grows these populations flock to urban areas, many of which are in coastal regions. Urbanization, in combination with the vulnerability characteristics of low socioeconomic status give little choice on where some people live. The most vulnerable populations, biophysically and socially are relegated to living in areas prone to flooding and other undesirable affects due to extreme weather events. These conditions have been seen in poor population both in Bangladesh and in New Orleans, particularly during Hurricane Katrina.[72]

A framework for understanding extreme heat vulnerability has recently been promoted using a local level bottom-up approach to vulnerability assessment. This framework incorporates ideas from scientific concepts in the climate change literature and highlights the process of identifying and understanding vulnerability of human health to heat waves and evaluating adaptive strategies.[73] Part of this framework is to understand how collective attitudes and decisions interact and build adaptive capacity to extreme heat events. Quantitative and qualitative data gathered at the local level can inform researchers on how local knowledge and traditional coping mechanism can influence the adaptation process. Building local level data using a mixed methods approach can incorporate quantitative date, such as heat mortality statistics and qualitative data, such as household surveys on preventive measures (e.g. air conditioning). Over time, a number of comparable case studies can help influence top-down (regional, nation and international) efforts that fill gaps left by local level efforts and improve bottom-up efforts.[73,74]

As one researcher put it, "ultimately, vulnerability is expressed at the individual level, however important the social and neighborhood context".[75] Public health researchers have agreed that there are gaps in knowledge to identifying vulnerable subpopulation[67] and that vulnerability assessments need to be comprehensive in identifying these populations as well as improving adaptive and mitigation efforts. As the number of extreme weather events continues to rise, more and more populations will be at risk from natural disasters. Although some populations may not be considered vulnerable now, after one extreme weather event, a population may become increasingly vulnerable each time such events occur. For example, in 1998 Hurricane Mitch devastated much of Honduras and Nicaragua causing damage equivalent to the countries' combined Gross Domestic Product, setting development efforts back many years.[73,76] Vulnerability is a multifaceted phenomenon and solutions must be multifaceted in addressing a broad range of social, cultural, demographic and economic conditions that often interact in complex ways. For example, structural mitigation includes protective engineering methods like seawalls, levees and dams while nonstructural mitigation can include regulating property development among at-risk areas and conserving features of the natural environment that provide protection. These adaptive efforts for addressing vulnerability require input from a variety of stakeholders including politicians, scientists, engineers and ultimately, the people who are vulnerable. Future research is needed and incorporating an interdisciplinary approach and approaches for identifying vulnerable populations may improve vulnerability assessment. New methods in geographical information systems (GIS) can help identify vulnerable populations and vulnerable systems in the built environment. Characteristics of each local region or neighborhood, in terms of social, economic and cultural factors, contribute to how that

community will respond to a disaster.[77] Climate change is a global problem that requires not only a global solution, but local community solutions, especially when identifying and protecting vulnerable populations.[57,72,75]

To characterize heat vulerability for this study a simple conceptual framework was used. The framework is couched in the contextual hazard of global warming and climate change which influence the first component of heat vulnerability, the exposure (for this study, heat waves and high ambient temperatures) (Figure 1.1). Exposure is directly related to the potential outcomes, those populations exposed to extreme heat events, considering the instensity and duration have potential outcomes. The outcomes are directly influenced by sensitivity of individual and environmental characteristics. The second chapter of this dissertation will focus on identifying individual and environmental risk factors for hospitalizations of heat-related illnesses. Adaptive capacities and responses also influence potential outcomes. Interventions such as air coniditioning use and heat-health warning systems may reduce the potential negative health outcomes assocaited with exposure to extreme heat. Chapter two will also examine ait conditioner use among identified at risk populations. Examining outcomes will be the focus on chapter three which will explore health outcomes as well as hospital resource use. Common comorbidities will be examined to identify how populations with these underlying medical conditions and a heat-related illness diagnosis further understand at risk populations. The fourth chapter will look specifically at the potential outcome of costs assocaited with hospitalizations and the cost effectiveness of interventions such as air conditioning and heat-health warning systems. By using the conceptial framework of vulnerability assessment this disseration will attempt to further identify specific sensitivities, potential outcomes and review responses and adaptive capacities in interactions to better understand how vulnerable populations are impacted by climate change and heat events.

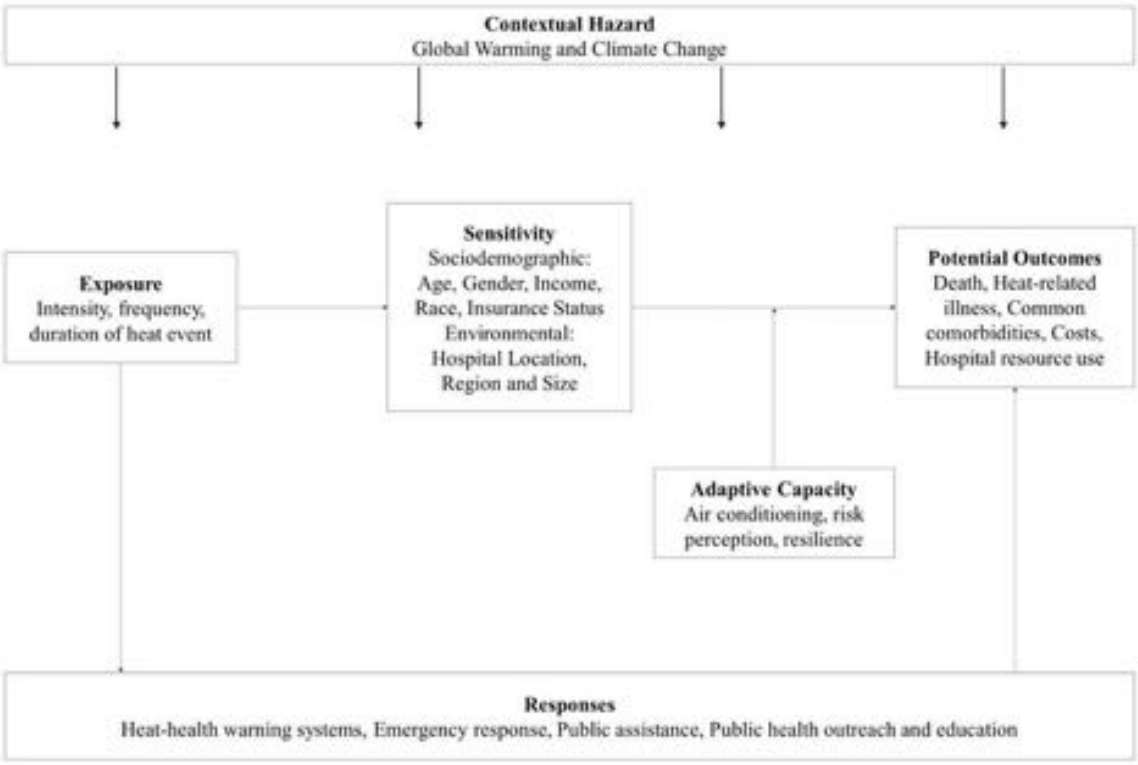

Figure 1.1. Heat –related illness vulnerability framework. Heat-related illness (outcome) is a result of exposure to extreme heat. Individual and environmental characteristics of hospitalizations (sensitivity) are examined to identify risk factors for vulnerable populations. At risk populations are also influenced by behaviors and interventions (adaptive capacities and responses), understanding responses helps to improve and reduce potential negative outcomes among populations vulnerable to heat-related illnesses.

1.4. Overview of the dissertation

1.4.1. Overall goals

To address limitations in the existing literature, this dissertation aims to identify risk factors for heat related morbidity and examine outcomes, such as hospital resource use and costs of hospitalizations due to heat-related illness in the United States from 2001-2010. Using a large administrative database that statistically represents all hospitalizations in the United States, this dissertation will give a robust description of risk factors for populations hospitalized and

diagnosed with heat-related illnesses which may differ significantly from those of heat mortality. The risk factors identified will enhance the above conceptual framework of vulnerability assessment by improving the sensitivity of vulnerable populations allowing for a better insight into those who are vulnerable during extreme heat events. Additionally, understanding aspects of protective factors such as air conditioner use will be explored and spatial analyzed among a number of vulnerable populations identified. This again will help in identifying the sensitivity of vulnerable populations while giving us information on the positive and or negative effects of adaptive capacities that are in place.

Many hospitalizations due to extreme heat events are due to direct heat illnesses, such as heat stroke a number of hospitalizations are also due to the exacerbation of underlying medical conditions. This dissertation will examine the outcomes of these common exacerbated conditions (diabetes, cardiac, respiratory and renal diseases) associated with a heat-related illness compared to those without a heat-related illness diagnosis to help explain whether HRI induced common comorbidities result in greater negative outcomes. Then, focusing on specifically cost, this dissertation will analyze current costs and estimate future costs associated with hospitalizations due to heat-related illness and explore potential cost effective options of air conditioner use and heat-health warning systems to reduce hospitalizations. By examining the potential outcomes we can improve on the conceptual framework of the vulnerability assessment by examining the interactions between sensitivity, potential outcomes and responses to these outcomes. This in turn will help to improve both the positive impacts of our response to extreme heat events and further benefit our adaptive capacities, potentially reducing negative health outcomes associated with hospitalizations of heat-related illnesses. These associations will also be beneficial to economists and policy makers to determine true and future costs of the impact of climate change on public health.

1.4.2. Specific aims

Specific aims are:

Aim 1a: To identify individual risk factors and document the pattern of heat-related illnesses through hospitalizations.

Aim 1b: To Identify sociodemographic factors in household cooling.

Hypothesis 1a: Regardless of etiology there is significant variability in HRI hospitalization patterning across sociodemographic and geographic catagories.

Hypothesis 1b: Air conditioner use and availability is limited among the elderly, low income and minority populations, those of which are most vulnerable to heat-related illnesses

Aim 2: To investigate outcomes and hospital resource use of heat-related illness hospitalizations and common comorbidities.

Hypothesis 2: Identified common comorbidities (i.e. diabetes, cardiac, respiratory and renal diseases) associated with HRIs have greater negative outcomes (e.g. death and discharge status) and use more hospital resources (e.g. length of stay and total charges) compared to the comorbidities that were not associated with a HRI diagnosis. **Aim 3: To examine the association of heat-related illness morbidity patterns and costs related to heat-related illness hospitalizations.**

Hypothesis 3: Costs associated with hospitalizations due to heat-related illness increase over study time period and will continue to increase as health impact due to climate change rise.

1.4.3. Organization of the dissertation

The subsequent part of the dissertation consists of four chapters. Chapter 2 introduces baseline demographic information on patient and hospital characteristics of the study population and used analytical approaches to identifying risk factors for hospitalizations and spatial patterns of air conditioning use (aim 1a and aim 1b). In Chapter 3, patient and hospital characteristics are analyzed for outcomes associated with heat-related illnesses and common comorbidities compared with just common comorbidities without a HRI diagnosis (aim 2). These analyses further refine characteristics of vulnerability established in Chapter 2. Chapter 4 focuses specifically on costs associated with hospitalizations due to heat-related illnesses by determining current costs and estimating future costs based on current predictive modeling of ambient temperature increases over time due to global warming (aim 3). Chapter 5 summarizes findings from Chapters 2-4 and discusses strengths and limitations of the study. The dissertation concludes with policy implications and recommendations for future research directions.

1.4.4. Significance of the dissertation

Individual and environmental risk factors for hospitalizations of heat-related illnesses identified in this dissertation add to the dearth of literature on heat morbidity. To my knowledge this is the first study to use a large administrative database of hospitalizations to identify risk factors for heat-related illnesses. As the science of matching large datasets improves, it will allow for more opportunities to explicate connections between theories and operationalization. This information can be used as a basis for understanding patterns of hospitalizations of heat-related illnesses which can be incorporated into vulnerability assessment models for extreme heat events. Additionally, by looking at both the risk factors for hospitalizations and the outcomes (discharge

status, total charges, etc.) of heat-related illness, this dissertation will yield a more complete profile of demographic and environmental characteristics for risk factors and identify additional shortcomings in current research. Lastly, the inclusion of monetary data on the actual and estimated costs of health effects due to climate change gives substantive evidence on the economic impact climate change will have on public health. Findings will benefit public health practitioners to design and implement more effective public health interventions taking into consideration risk factors, outcomes, economic costs and the already limited resources available to combat the health impacts of climate change.

1.5. Data sources and study population

The main data source for the study population was of hospital discharge records 2001-2010 from the Nationwide Inpatient Sample (NIS) which was developed as part of the Healthcare Cost and Utilization Project (HCUP) in partnership with the Agency for Healthcare Research and Quality (AHRQ). The NIS is the largest all-payer care database, with data from approximately 8 million hospitalizations per year (about 20% of all hospital discharges in the United States).[78] The NIS includes data on patient demographics and hospital characteristics, primary and secondary diagnoses coded according to the *International Classification of Diseases, Ninth Revision* (ICD9) (with up to 15 diagnoses available for the years 2001-2008 and up to 25 diagnoses for 20092010), primary and secondary procedures (ICD-9 coding up to 15 diagnoses available for the years 2001-2008 and up to 25 diagnoses for 2009-2010), type and source of admission, discharge disposition, primary payer type, total hospital charges, and length of stay. Stratification and weighting variables allow calculation of national estimates and account for the complex sampling design.[79]

For chapter 2 and chapter 4 the study population for HRI consists of patients in the 2001-2010 NIS with at least one diagnosis of a heat-related illness (ICD-9 codes 992.0 – 992.9) from 2001 to 2010. The control group for chapter 2 consisted of all other NIS hospitalizations during this time period. Since approximately 95% of all HRI hospitalizations occurred in the summer months (May-September), all hospitalizations not occurring during these months were excluded. For chapter 3, the study population consists of patients who had a primary or secondary diagnoses of diabetes (ICD-9 code 250.00), cardiovascular diseases (ICD-9 codes 390-398, 402, 404-448), respiratory illnesses (ICD-9 codes 460-519), nephritic illnesses and acute renal failure (ICD-9 codes 580-589) along with a diagnosis of a heat-related illness (ICD-9 codes 992.0992.9). Data on air conditioner use and total cost of electricity use from air conditioning was derived from the Residential Energy Consumption Survey (RECS), a national household survey conducted by the United States Energy Information Administration (EIA) starting in 1978. In 2005 and 2009 surveys were collected from approximately 4,000 and 12,000 households, respectively, which were nationally representative of the 110 million residential U.S. households.[80] The variables from the RECS used in this study include census region, state, air conditioner use, total cost of electricity for air conditioner use and householder age, poverty status and employment status. Chapter 2 focused on the spatial patterns of air conditioner use among households in the United States among 4 U.S. Census regions. Chapter 4 consisted of total costs of electricity for air conditioner use among state and state groupings as defined by the RECS.

Chapter 2. Identifying individual risk factors and documenting the pattern of heat-related illness through hospitalization and spatial patterns of household cooling

2.1. Introduction

Heat from high environmental temperatures is a natural hazard that can adversely affect human health.[1-4] Human populations have acclimatized to a variety of local climates physiologically and behaviorally, though there are limits to the extremes in temperature the human body can tolerate. An individual's ability to thermoregulate protects the body from ambient temperatures by maintaining a core body temperature around 36.0°C to 37.5°C.[5] Body temperatures outside of this range are classified as either hypothermia (body temperature below 35.0°C) or hyperthermia (body temperature above 37.5°C).[6,7] Heat-related illnesses (HRIs) - usually termed heat stress, heat exhaustion and heat stroke - include a range of signs and symptoms within the broader

definition of hyperthermia. Heat stress is a perceived discomfort and physiological strain; heat exhaustion, a mild to moderate illness; and heat stroke, a severe illness characterized by a core body temperature above 40.0°C.[7] Clinically, severe heat illness can be seen as a combination of systematic inflammatory response and cytotoxicity, which left untreated results in multiple organ failure.[5,7,8] Infants are at increased risk of heat-related morbidity and mortality as are the elderly, individuals taking medications that interfere with thermoregulation, those with underlying medical conditions such as cardiac, respiratory, renal disease or diabetes.[4,9-11]

Studies of heat mortality during specific events, such as the 1995 Chicago heat wave and the 2003 heat wave that affected much of Europe, highlight characteristics of populations that are at risk of dying during extreme heat events. During the 1995 Chicago heat wave, Semenza et al., described heat mortality among the elderly, those with known medical conditions such as cardiovascular and respiratory disease, individuals confined to bed, unable to care for themselves and with social risk factors such as not leaving the home daily, living alone, and limited social networks.[12] Similar populations were affected in and around Paris, France during the August 2003 heat wave.[13] Regression models of time series data quantifying excess mortality during heat events show that mortality rises as temperature exceeds a certain threshold.[14-16] Study methodologies using mortality end points identify risk factors for heat mortality such as being elderly, of a lower socioeconomic status, or a person of color or having an underlying medical condition (cardiovascular, cerebrovascular, respiratory, renal, neurological diseases, and diabetes).[17-19] However, the diagnosis of a specific heat-related illness is not always confirmed during heat events and diagnoses for cause of death are primarily due to the exacerbated underlying medical condition (e.g. cardiovascular disease, respiratory disease, etc.).[20-23] While relatively few studies have examined heat-related morbidity most heat morbidity studies have

used methodologies that incorporate heat-related illness diagnoses and show a stronger relationship between the risk factors and outcomes. These associations also highlight a number of protective factors for HRIs.

Some studies of heat-related morbidity have focused on emergency dispatch data and emergency department visits during individual heat events, with specific HRI diagnoses,[24-27] while others have analyzed excess hospitalizations during specific extreme heat events.[19,28,29] While there has been increased research attention on the health outcomes associated with extreme heat events, few investigations have identified risk factors that lead to HRI hospitalizations, particularly those comparable among different geographic regions mainly due to the difference in the classification of heat events across regions.[30,31] Additionally diagnoses of HRIs are often under-reported as the underlying medical conditions are often considered the primary diagnoses during a hospitalization while the HRI diagnosis may be noted as secondary or not recorded at all limiting our understanding and knowledge of heat-related illnesses.[32,33]

One of the strongest preventive measures to HRIs is ownership and use of an air conditioner during extreme heat events.[34-36] As of 2009, 87% of homes in the United States have air conditioning, although the prevalence of AC is lower (and less efficient cooling systems higher) among apartment dwellers and low income households.[37] A recent Morbidity and Mortality Weekly Report (MMWR) highlighting heat illness and deaths in New York City indicated that a majority of heat illness decedents did not have a working air conditioner, although information on cooling practices of decedents was limited.[38] Research is needed regarding a number of socioeconomic and behavioral issues that might improve access to air conditioning and reduce heat mortality and morbidity.[39,40]

In addition to individual level determinants and behaviors around cooling during extreme heat events, the environment plays a key role in exacerbating or protecting us from extreme heat events. While the urban heat island (UHI) is not a new concept, it has been used to explain higher rates of HRI in urban areas as compared to rural areas, due to the urban landscape, including lack of vegetation and impervious surfaces covering large areas.[41,42] The average ambient urban temperature is increased where vegetation has been replaced by heat-retaining materials such as asphalt and concrete. Recent studies using remote sensing and spatial analysis attempt to create heat vulnerability maps and indexes based on environmental factors.[43-45] An integrated understanding of environmental factors, individual level factors and socio-behavioral determinants is needed to accurately identify populations most vulnerable to extreme events due to climate change.

Climate change has initially affected vulnerable populations, but the increase in frequency and magnitude of climate change associated heat events ultimately disrupt and affect all populations. Using the conceptual framework discussed in chapter one, this chapter will specifically examine the sensitivity of a population and how these factors, both individual and environmental characteristics can help determine at risk populations from exposure to extreme heat events (Figure 2.1). The sociodemographic and environmental characteristics examined have a direct influence on heat-related illness hospitalizations. This research examines specific health outcomes due to climate change, heat waves, by identifying risk factors, discussing preventable measures and informing policy recommendations to prevent HRIs and adapt to extreme heat events. This study examines heat-related morbidity using a large nationally-representative administrative database to identify individual and environmental risk factors for hospitalizations due to HRI and document the pattern of household cooling. This analysis aims to identify public

health strategies for reaching populations vulnerable to heat morbidity and preventing illness and death during future heat events.

2.2. Methods

2.2.1. Data sources

The primary source of data for this study was the 2001 to 2010 Healthcare Cost and Utilization Project (HCUP) Nationwide Inpatient Sample (NIS), which was developed by the Agency for Healthcare Research and Quality (AHRQ). The NIS is the largest all-payer care database, with data from approximately 8 million hospitalizations per year (about 20% of all hospital discharges in the United States).[46] The NIS includes data on patient demographics and hospital characteristics, primary and secondary diagnoses coded according to the *International Classification of Diseases, Ninth Revision* (ICD-9) (with up to 15 diagnoses available for the years 2001-2008 and up to 25 diagnoses for 2009-2010), primary and secondary procedures (ICD-9 coding up to 15 diagnoses available for the years 2001-2008 and up to 25 diagnoses for 2009-2010), type and source of admission, discharge disposition, primary payer type, total hospital charges, and length of stay. Stratification and weighting variables allow calculation of national estimates and account for the complex sampling design.[46,47]

This data includes information on urban vs. rural hospital location. Additional spatial data for geocoded hospital location was obtained from ESRI based on American Hospital Association (AHA) identifiers, and merged to the NIS dataset to create an updated hospital location variable. Using the 2010 Census Urban and Rural classification, geocoded hospitals were mapped and designated as being in urbanized areas of 50,000 or more people, in small urban clusters of 2,500 to 50,000 people or in rural areas which encompassed all populations outside urbanized areas

and small urban clusters.[48] This updated definition was created to determine if environmental factors like high and low urban populations and rural populations differed in HRI hospitalizations. All maps were created using ArcGIS (version 10; ESRI, Redlands, CA). Data on spatial patterns of air conditioner use was derived from the Residential Energy Consumption Survey (RECS), a national household survey conducted by the United States Energy Information Administration (EIA) every three years starting in 1978. In 2005 and 2009 surveys were collected from approximately 4,000 and 12,000 households, respectively, which were nationally representative of the 110 million residential U.S. households. The variables from the RECS used in this study include census region, state and air conditioner use.

2.2.2. Subjects and definitions

The study population for HRI consists of patients in the 2001-2010 NIS with at least one diagnosis of a heat-related illness (ICD-9 codes 992.0 – 992.9) from 2001 to 2010. The control group consisted of all other NIS hospitalizations during this time period. The HRI variable was coded as a binary indicator variable. The initial cohort consisted of 15,885 discharge records for heat-related illness (HRI) and 79,140,110 discharge records for control comparison. Since approximately 95% of all HRI hospitalizations occurred in the summer months (May-September), all hospitalizations not occurring during these months were excluded yielding a final cohort of 14,949 HRI discharge records and 37,019,792 controls.

2.2.3. Statistical analyses

The outcome variable was heat-related illness. First, a descriptive analysis of baseline characteristics was performed for HRI and control populations. Second, multivariable analysis

was performed to determine risk factors associated with heat morbidity. A log-binomial model, which directly models risk ratios (RRs), was used. Analyses were weighted for national estimates and to enhance the log-binomial approach for maximum likelihood estimates and likelihood ratios.[49] Risk factors for heat-related illnesses were explored, including patient characteristics (gender, age, race, zip code income quartile, insurance), hospital characteristics (hospital bed size, hospital location, hospital region), and comorbidities. Patient comorbidities were coded and assessed using the AHRQ algorithms based on methods developed by Elixhauser et al.[50] Third, a multilevel model was used to account for clustering of patients within hospitals. Weighted samples were not used for multilevel analysis as recommended by the HCUP hierarchical modeling report.[51] Lastly a spatial analysis was performed to visually represent HRI hospitalizations among hospital clusters. A spatial analysis was also performed with RECS air conditioner data to analyze the use of air conditioning among vulnerable populations and to compare this to findings from the analysis of risk factors for hospitalizations due to HRI. All statistical analyses were performed using SAS 9.3. This study was approved by the Institutional Review Board of Hunter College, CUNY and conforms to the HCUP data use agreement.

2.3. Results

2.3.1. Demographic and hospital characteristics

The characteristics of patients with HRI and of all hospitalized patients during the five "summer" months from 2001 to 2010 in the NIS data are shown in Tables 2.1 and 2.2. After weighting there were 73,185 patient discharges for HRI and 181,094,795 for all other discharges during this time period. Compared to all non-HRI hospitalizations, more HRI admissions were emergencies. Emergency department (ED) admission (the source) accounted for 59% for HRI hospitalizations and 34% of non-HRI hospitalizations, while emergency admission (as type of admission)

accounted for 73% for HRI and 41% of non-HRI hospitalizations The mean age was also higher for HRI than non-HRI hospitalizations, 55 years compared to 48 years. The number of HRI hospitalizations increased faster than non-HRI hospitalizations, albeit with large year to year variation (Figure 2.2).

2.3.2. Multivariable analysis of risk factors for heat-related illness hospitalization

Multivariable analyses identifying risk factors for patients with an HRI diagnosis and any other hospitalization are shown in Table 2.3. The multivariable model included race, age, gender, zip code income quartile, insurance, common comorbidities (congestive heart failure, chronic pulmonary disease, diabetes, hypertension, neurological disorders, renal failure and psychoses), and hospital characteristics including region, bed size, and hospital location (urbanize area, small urban cluster or rural). Blacks, 1.21 (95% CI: 1.19-1.23), males 3.54 (95% CI: 3.49-3.58) and patients above the age of 40 (ages 40-64) 1.34 (95% CI: 1.32-1.37), (ages 65-74) 1.28 (95% CI: 1.25-1.30), (ages 75+) 1.52 (95% CI: 1.47-1.55) had higher risk of HRI hospitalizations. Patients who lived in zip codes with the lowest median income quartile were more likely to be hospitalized for a HRI, 1.19 (95% CI: 1.17-1.21) as were those in the second median income quartile 1.08 (95% CI: 1.07-1.10). Lack of health insurance was a particularly strong predictor of being hospitalized due to HRI, 2.33 (95% CI: 2.29-2.37).

Patients with neurological disorders and psychoses were more likely to be hospitalized with HRI, with a relative risk of 1.79 (95% CI: 1.75-1.82) and 1.83 (95% CI: 1.79-1.87) respectively. Other comorbidities such as diabetes, renal failure and respiratory diseases did not predict HRI relative to non-HRI hospitalizations with risk ratios of 0.80 (95% CI: 0.78-0.82) for congestive heart failure, 0.72 (95% CI: 0.71-0.82) for chronic pulmonary diseases, 0.90 (95% CI: 0.89-0.92) for diabetes, 1.00 (95% CI: 0.99-1.01) for hypertension and 0.61 (95% CI: 0.60-0.63) for renal

failure. Examination of hospital characteristics indicate that patients in the Western U.S. region had higher risk of HRI hospitalization, 1.23 (95% CI: 1.20-1.25) as did small, 1.39 (95% CI: 1.37-1.42) and medium sized hospitals, 1.25 (95% CI: 1.23-1.27) and located in rural areas, 1.79 (95% CI: 1.74-1.83) or small urban clusters, 2.09 (95% CI: 2.06-2.12).

2.3.3. Multilevel analysis of risk factors for heat-related illness hospitalization

The multilevel analysis (Table 2.4.), found risk ratios similar to the single-level multivariable analysis. Blacks, (RR 1.17, 95% CI: 1.08-1.27), males (RR 3.55, 95% CI: 3.35-3.77) and patients above the age of 40 (ages 40-64) (RR 1.29, 95% CI: 1.19-1.40), (ages 65-74) (RR 1.15, 95% CI: 1.04-1.27), (ages 75+) (RR 1.40, 95% CI: 1.28-1.53) were at significantly higher risk of HRI hospitalizations after accounting for clustering within hospitals. Being in the lowest zip code income quartile was significantly predicted of HRI at 1.13 (95% CI: 1.03-1.25) as did being uninsured (RR 2.51, 95% CI: 2.31-2.72) in the multilevel analysis. Hospital level characteristics for the multilevel analysis also had similar results with small hospital size having a relative risk of 1.35 (95% CI: 1.19-1.53) and medium hospital size a relative risk of 1.17(95% CI: 1.05-1.30). Both the South and West were associated with an elevated risk of 1.13 (95% CI: 0.96-1.32) and 1.12 (95% CI: 0.94-1.32) respectively for HRI hospitalization. Risk of HRI hospitalization in rural areas and small urban clusters also remained higher than in urban areas.

2.3.4. Spatial analysis of heat-related illness hospitalization and household cooling

The spatial analysis for incidence of HRI hospitalizations from 2001 to 2010 by hospital location is shown in Figure 2.3. Darker shades on the map show a higher incidence of HRI hospitalizations per square mile based on hospital address, with lighter shades indicating lower

rates of HRI hospitalization. Figure 2.4. shows air conditioner use among households whose income was 100% below the poverty line for 2005 and 2009. While overall air conditioner use for all households increased from 82% in 2005 to 87% in 2009, households 100% to 150% below the poverty line had 3% to 6% decrease in owning an air conditioner from 2005 to 2009 compared with households above the poverty line. Air conditioner use among householders unemployed, retired or employed part-time (not shown in Figure 2.4.) showed a 25% overall decrease in owning an air conditioner from 2005 to 2009, compared to householders employed full-time (based only on survey results). Additionally, air conditioner use increased among householders of most age groups from 2005 to 2009, but decreased by 13% among householders 75 and older.

2.4. Discussion

Most of the individual risk factors for heat related morbidity that were identified were similar to those previous heat-related morbidity and mortality studies.[32,52,53] For instance individuals identified as African American, the elderly, and those living in zip codes at the lowest income quartile were at a higher risk for hospitalizations due to heat-related illnesses. However, the nationally representative data yielded some surprising findings as well. Males were over 3 times more likely than females to suffer HRI hospitalization, though much of the prior research has found that females were more likely to suffer from heat-related mortality and morbidity. Results also showed that all age groups over the referent group were at an increased risk of heat-related illness as compared to 18-39 year olds. Prior studies have frequently highlighted infants and elderly as being most vulnerable, especially to heat mortality, but I found that all adults 40 years old and over were at somewhat elevated risk for HRI hospitalizations.

This increased risk of hospitalization among middle-aged adults, not just the elderly may signify a lack of risk perception among the population in regards to heat-related illness. Studies have shown that adults and many elderly populations do not perceive themselves as at risk for a HRI. Many of the signs and symptoms of heat stress or heat exhaustion may go unnoticed or be attributed only to a lack of proper hydration. These early signs can quickly advance to a more serious illness without proper medical attention or cooling.

Heat is the number one cause of death from natural disasters in the United States, and is often overlooked due to the limited visibility of heat as a hazard.[54] Tornados, hurricanes, floods and blizzards are more tangible and dramatic than heat. Future intervention strategies and policy should increase awareness of heat as a significant health risk. Public health outreach and education can enhance the response to extreme weather events, such as heat waves, thereby improving potential outcomes both by improving the understanding of heat waves and knowledge concerning the risk perception and behaviors of vulnerable populations. Environmental factors that increase the risk of heat morbidity (e.g. built environment, geography) should also be identified and where possible ameliorated. Important discussions and decisions will need to center around urban design and land use as potential factors that influence our adaptive capacity and response to extreme heat events. The urban heat-island effect is one such factor influencing the risk of heat morbidity, though other structural changes such as green roofs and increase green space will also have an effect on heat morbidity and mortality. Much research has been done on the urban heat island effect and its implications on heat-related illness; though this study indicates that heat morbidity is not restricted to urban environments. Risk of hospitalization due to HRI was actually higher in small urban clusters (populations 2,500 to 50,000) and rural areas as compared to urban areas (populations 50,000+). Additional research

into heat morbidity is needed to fully understand why risk of hospitalization due to HRI is higher in small urban clusters and rural areas, more so than urban areas, despite the fact that urban areas have higher temperatures than surrounding areas, and hold that heat for longer periods of time. Hospital travel distance, absent heat-health warning systems and lower health literacy outside of urban areas may explain these differences.

Accounting for the hierarchical nature of the data improved the robustness of the analysis allowing consideration of the interacting effects of patient and hospital characteristics. Future analyses might include additional hospital-level and environmental-level variables to determine how factors such as patient or hospital location influence HRI risk. Surprisingly, I found that common serious comorbidities, aside from neurological disorders and psychoses, were not a significant risk factor for being hospitalized for a heat-related illness compared to all other hospitalizations. This is contrary to previous research indicating that these common comorbidities are exacerbated during extreme heat events. This should be interpreted cautiously as it may indicate only that other hospitalizations (i.e. our comparator) are very frequent for persons with "chronic" medical conditions. Additionally artifacts may have been introduced if the severity of the underlying condition led providers to code these conditions and underdiagnose or under-code HRI. Such underreporting can lead to gaps to further understanding of risk factors for heat-related illnesses, especially in vulnerable subpopulations. Current policies regarding diagnostic procedures during heat events should be examined to increase awareness among emergency personal and physicians to improve diagnoses of heat-related illnesses. Our results also indicate that individuals from poorer neighborhoods and especially persons without insurance are at an increased risk of hospitalizations due to heat-related illnesses. As pervasive as air conditioning use has become in the United States, many among these vulnerable populations still lack access to this protective factor. Our spatial and descriptive analysis of air conditioning

data found that poor and elderly individuals as well as those who are unemployed or underemployed have lower rates of air conditioning. These same populations are at the highest risk of being hospitalized for heat-related illnesses. In some communities air conditioning is still thought of as a luxury, but the increase in extreme heat events may make air conditioning a necessity. Steps are needed to improve the availability and affordability of air conditioning and to improve access to cooling centers. Policy surrounding energy consumption during summer months and during heat events will become an important topic as the demand for energy increases and further stresses energy distribution systems around the United States. Although this study is the first to assess nationally representative data on HRI, there are limitations. Administrative data is not as accurate as clinical data and HRI is almost certainly under-coded. Because the NIS does not capture information regarding hospital readmission, an individual can be counted multiple times if hospitalized for an HRI during different time periods. Because I was unable to account for clustered patient data, this may cause narrower confidence intervals, though given the large data set and rarity of heat-related illness diagnoses I believe it would not make much difference in the overall analysis. Additionally, the RECS data does not link specifically with NIS records due to different levels of measurement (individual versus household) thus comparisons can only be made at an ecological level. Additionally, reporting for some hospital level variables varies from state to state.

In summary, risk factors for heat morbidity differ from those of heat mortality. Using the NIS database, I identified a number of previously unknown risk factors for heat morbidity HRI, including age greater than 40, males and hospitalization in rural areas and small urban clusters. Epidemiological and spatial analytic techniques can help identify targets for policy interventions and future research.

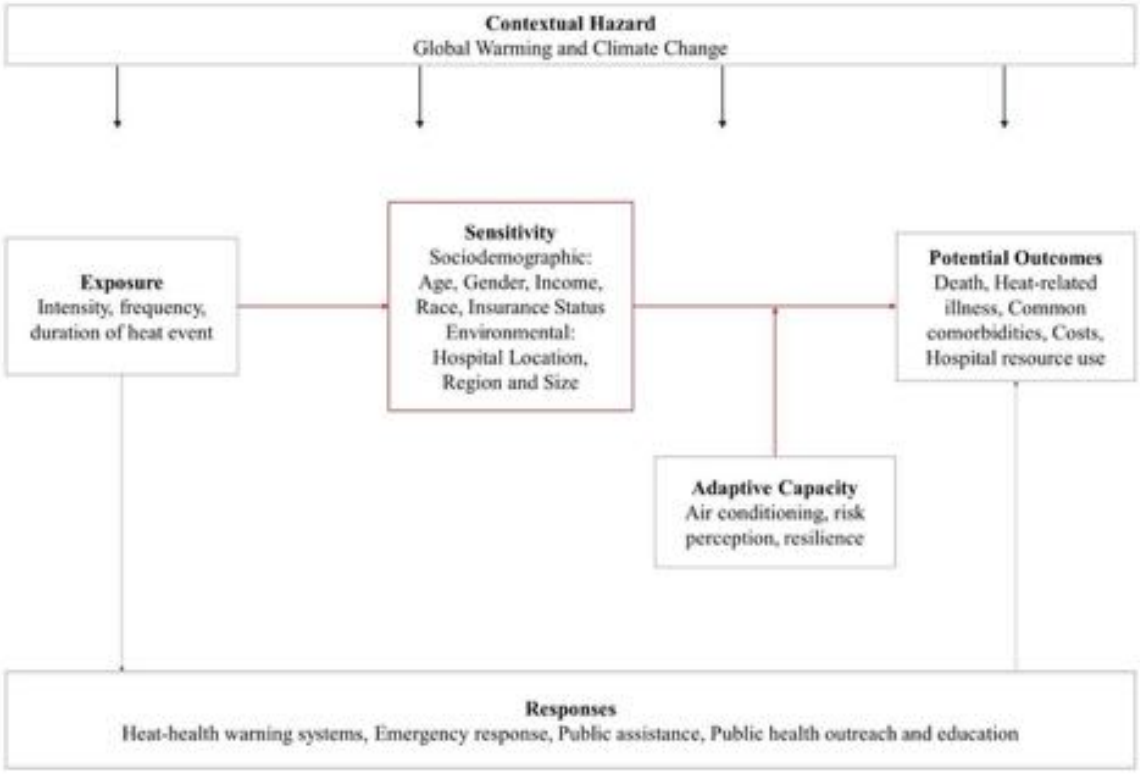

Figure 2.1. Risk factors associated with hospitalizations of heat-related illnesses. Identifying risk factors for hospitalizations of heat-related illness improves understanding of populations vulnerable to heat morbidity. Air conditioning use, a preventative measure, among vulnerable populations is examined as a potential adaptive capacity for influencing potential negative outcomes.

Chapter 3. Investigation of outcomes and hospital resource use of heat-related illness hospitalizations

3.1. Introduction

According to the latest Intergovernmental Panel on Climate Change (IPCC) global mean temperature is projected to increase between 1.5 and 2.3°C by mid-century and over 4°C by the end of the century.[1] High ambient temperature and extreme heat events worsen human health and are associated with excess mortality and morbidity through a range of heat-related illnesses (HRI) and exacerbations of underlying medical conditions.[2,3] The

The effect of high temperature on morbidity is a significant public health issue and is associated with a large number of hospitalizations each year.[4,5] Although hospitalizations from direct heatrelated illnesses such as heat exhaustion and heat stroke are notable, there are significant hospitalizations due to exacerbated underlying medical conditions such as cardiovascular diseases, respiratory diseases and renal diseases.[6-9] In addition, urban residents may be at higher risk for heat morbidity due to the "urban heat island effect" resulting from higher absorption of heat among dark paved surfaces and buildings and the potential for higher concentrations of air pollutants.[10-12]

The previous chapter spoke at length concerning risk factors for heat-related illness hospitalizations, though the current chapter will now examine what are the potential outcomes related to hospitalizations due to heat-related illnesses. Additionally this study will explore some of the common comorbidities that are exacerbated. While heat-related illness hospitalizations spike during extreme heat events, excess hospitalizations for underlying medical conditions, as mentioned above, increase as well. Researchers in Taiwan showed that hospital admissions for

kidney disease increased by 27% among all age-groups for ambient temperatures at or above 30°C.[13] Green et al. estimated relative risks of hospitalizations in California increased for acute renal disease (7.4%) and diabetes (3.1%) per 10°F increase above mean daily ambient temperature.[14] In Melbourne Australia acute myocardial infarction admissions to hospitals increased by 10% for one-day daily average temperatures of 30°C.[15] A recent study in the United States showed that heat-related hospitalizations for respiratory diseases in the Medicare population increased by 4.3% per 10°F increase in mean daily temperature.[7] Similarly a study in New York City showed that when temperatures exceeded 28.9°C hospital admissions for respiratory diseases increased by up to 2.7% per °C above the threshold temperature(28.9°C).[8] Additionally, current research into how heat events affect individuals with Type 2 Diabetes indicate that they are more susceptible to hospitalization during these events due to impaired thermoregulation due to the illness and prescribed medications.[16]

Heat-related illnesses are a significant cause for hospitalizations during heat events though underlying medical conditions may mask the initial heat-induced reason for the hospitalization. Hospitalizations from direct heat illness have deleterious consequences as seen during the 2003 heat wave in France with patients, especially elderly individuals, having reduced survival rates even 1 or 2 years after the initial hospitalization.[17] Patients with underlying medical conditions that are exacerbated by heat may increase the likelihood of greater negative outcomes including permanent disability and death. By using the conceptual framework for vulnerability assessment this chapter will explore potential outcomes and assess whether individuals diagnosed with a heat-related illness and common comorbidity, including diabetes, cardiovascular disease, respiratory disease and renal disease have greater negative outcomes than individuals hospitalized with only the common comorbidity thus improving knowledge concerning heatrelated morbidity and providing opportunities for intervention to prevent heat-related illness. Information on the

potential outcomes, specifically in identifying patients and populations with underlying medical conditions that are sensitive to extreme heat, will improve our ability to assess and intervene for at risk populations vulnerable to hospitalization due to heat-related illnesses (Figure 3.1).

3.2. Methods

3.2.1. Data Sources

The primary source of data for this analysis was the 2001 to 2010 Healthcare Cost and Utilization Project (HCUP) Nationwide Inpatient Sample (NIS), which was developed by the Agency for Healthcare Research and Quality (AHRQ). The NIS is the largest all-payer care database, with data from approximately 8 million hospitalizations per year, or about 20% of all hospital discharges in the United States.[18] The NIS contains data on patient and hospital demographic characteristics, primary and secondary diagnoses (*International Classification of Diseases, Ninth Revision* [ICD-9-CM] coding up to 25), primary and secondary procedures (ICD-9-CM coding up to 25), type and source of admission, discharge disposition, primary payer type, total hospital charges, and length of stay. Stratification and weighting variables allow calculation of national estimates, accounting for the complex sampling design and the expanded sampling framework over time.

3.2.2. Subjects and Definitions

The study population consists of patients who had a primary or secondary diagnoses of diabetes (ICD-9 code 250.00), cardiovascular diseases (ICD-9 codes 390-398, 402, 404-448), respiratory illnesses (ICD-9 codes 460-519), nephritic illnesses and acute renal failure (ICD-9 codes 580589) along with a diagnosis of a heat-related illness (ICD-9 codes 992.0-992.9). The major disease groupings chosen were consistent with previous heat wave hospitalization studies, notably

Semenza, et al. 1999 and Knowlton, et al. 2009.[4,19] Since approximately 95% of all HRI hospitalizations occurred in the summer months (May-September), all hospitalizations not occurring during these months were excluded. Each disease group (diabetes, cardiac, respiratory and renal diseases) hospitalization was compared to the disease group with a diagnosed heatrelated illness.

3.2.3. Statistical Analysis

Outcome and hospital resource use dependent variables analyzed included length of stay, number of procedures, total charges, discharge status and death. Discharge status was categorized as a binary variable for either a routine or non-routine hospital discharge. Analyses for discharge status calculated the risk of having a non-routine discharge, which included transfer to a rehabilitation facility or specialty hospital, discharged with home health care, discharged against medical advice or discharged to court/law enforcement. The first analyses were descriptive statistics of outcomes for heat-related illnesses, disease grouping without a HRI diagnosis, and disease groupings with a HRI diagnosis. Secondly univariate and adjusted multivariable analyses were performed for each dependent variable. Analyses compared disease grouping outcomes versus the outcomes of disease groupings with a heat-related illness. Continuous outcomes, including length of stay, number of procedures and total charges, were analyzed with linear regression models. Binary outcomes, death and discharge status, were analyzed with a logbinomial model, which directly models risk ratios (RRs). Multivariable models included independent variables of sociodemographic characteristics (gender, age, race, zip-code income quartile and insurance status) and hospital characteristics such as geographic region (Northeast, Mid-West, South, West) and hospital location (rural, small urban cluster, and urban area). The final analyses consisted of linear and log-binomial regressions for stratified variables including

gender, age category, race, zip-code income quartile, insurance status, hospital location and geographic region. Comparators for analyses were all other hospitalizations without a HRI diagnosis and all other hospitalizations for comorbidities without a co-diagnosis of a HRI and the common comorbidity (e.g. diabetes). For example, males hospitalized with diabetes and a HRI were compared to males who were only hospitalized for diabetes and similarly for each of the stratified analysis.

All statistical analyses were performed using SAS 9.3. This study was approved by the institutional Review Board of Hunter College and conforms to the HCUP data use agreement.

3.3. Results

3.3.1. Discharge Characteristics

Sociodemographic characteristics and hospital characteristics for heat-related illness hospitalizations and disease grouping hospitalizations with and without a HRI diagnoses are found in the Appendix. Compared to hospitalizations of disease groupings (diabetes, cardiac, renal and respiratory diseases) alone, characteristics of hospitalizations of disease groupings with an HRI diagnoses were more similar to those of heat-related illness hospitalizations alone. One difference being that males were more likely to be hospitalized with a HRI compared to all other hospitalizations. There were a large number of cases for each disease grouping without a HRI diagnoses compared to the diseases groupings with a HRI diagnosis. Diabetes with a heat-related illness diagnoses only consisted of 384 cases which limited some analyses. For cardiac diseases with an HRI diagnoses there were 1819 cases. There were also some differences particularly among the youngest age category for cardiac diseases, which include fewer cases than those patients with just a heat-related illnesses diagnosis, 0.78% vs. 4.45% respectively. Respiratory

diseases with an HRI diagnosis consisted of 1430 cases and renal diseases with an HRI diagnosis included 2485 cases.

3.3.2. Univariate and multivariable model outcomes: Heat-related illness and common comorbidities

Comparative analysis for unadjusted and adjusted outcomes can be seen in tables 3.1.1., 3.1.2., 3.1.3., 3.1.4. and 3.1.5. for HRIs and disease groups, diabetes, cardiac, renal and respiratory diseases, respectively. The dependent variable for each outcome was modeled for having either a HRI or a disease grouping and a HRI diagnosis compared to not having the diagnosis among hospitalized populations. Multivariable models included independent variables such as age, gender, race, zip code income quartile of patient, insurance status, hospital location and geographic region. Outcomes of heat-related illnesses and all other hospitalizations during the time period showed no increase in length of stay, number of procedures, or total charges. Additionally there was no elevated risk of death or non-routine discharge among heat-related illness hospitalizations compared to all non-heat-related illness hospitalizations. Similar results were seen in the disease groupings, diabetes, cardiac and renal diseases with HRI diagnoses, no increase in length of stay, number of procedures or total charges and no elevated risk of death or non-routine discharges compared to diseases groupings, diabetes, cardiac and renal diseases with no HRI diagnoses.

Respiratory diseases with an HRI diagnoses showed increased number of procedures, 0.29 and increased total charges $5027 in addition to a 21% higher risk of death compared with only a respiratory disease diagnosis in the unadjusted model. When adjusted with independent variables respiratory diseases with an HRI diagnosis still showed an increased number of procedures, 0.19,

a 34% increased risk of death and a 7% increased risk of non-routine discharge. Total charges increased by $4378, though this result was not statistically significant.

3.3.3. Stratified Multivariable model outcomes: Heat-related illness and common comorbidities

Stratified multivariable model analysis outcomes are shown in tables 3.2.1., 3.2.2., 3.2.3.. 3.2.4. and 3.2.5. Similar to the above analysis the dependent variable for each outcome was modeled for having either a HRI or a disease grouping and HRI diagnosis compared to not having the diagnosis among hospitalized populations. Heat-related illness diagnoses and each disease grouping with HRI diagnoses were stratified by gender, age category, race, zip code income quartile of patient, insurance status, hospital location and geographic region.

Outcomes for heat-related illness hospitalizations showed increased total charges for age group 0-17 year olds by approximately $7000 compared to non-heat-related illness hospitalizations during this time period. This age group also showed an increased risk of death and non-routine discharge, though not statistically significant. Age groups, 18-39 year olds showed a 2-fold increased risk of dying due to HRI hospitalization and 40-64 year olds showed a 4% increased risk of death due to HRI hospitalization all compared to non-heat-related illness hospitalization. Patients who were uninsured and had a HRI had more than 2 times the risk of dying than those without a heat-related illness diagnosis. Discharge records in the West showed patients have a 16% increased risk of death, though all other hospital locations and regions were at a reduced risk.

Cases with a diagnosis of diabetes and a heat-related illness showed an increase in the number of procedures, 2.72 more, among the youngest age group, 0-17 year olds, while all other outcomes were elevated but not statistically significant. Results from risk of death among patients with a diagnoses of diabetes and HRI were inconclusive due to very few deaths among this population.

Females, in addition to 0-17 year olds had an increased risk of death with a renal disease diagnosis and heat-related illness. Increased risk of death was also seen among males, 18-74 year olds, Black, Hispanic, and those identifying as Other (including Asian/Pacific Islander and Native Americans) for diagnoses of cardiac diseases with a heat-related illness, compared to those with only a cardiac disease diagnosis. Additionally, patients in the lowest zip code income quartiles were 60% more likely to die, as were those without insurance, almost 2.5 times the risk. Patients in urban areas had a 12% increased risk and those in the West had a 48% increased risk of death compared to those patients with only a diagnosis of cardiac disease and no heat-related illness. There were a number of elevated outcomes for patients diagnosed with a respiratory disease and a heat-related illness. A greater number of procedures were shown for females, 0-39 year olds, Black and Hispanics, compared to patients with only a respiratory disease diagnosis. Total charges were also higher among Blacks (> $28,000), and those in the median zip code income quartile (> $28,000) for hospitalizations of a respiratory disease and heat-related illness compared to those hospitalized for just a respiratory disease. Increased risk of death was shown for males and among all racial groups. Age group 0-17 year olds showed a 6.5 times increased risk, 18-39 year olds showed a 5.5 times increased risk and 40-64 year olds showed a 17% increased risk of death in addition to an increase in non-routine discharges among these age groups for respiratory diseases and HRI diagnosis. The lowest two zip code income quartiles showed a 37% and 36% increase in risk of death and an increased risk of non-routine discharge for those diagnosed with a respiratory disease and HRI compared to those with just a diagnosis of a respiratory disease. Additionally patients hospitalized in urban areas showed an increased risk of death, 26%, and increased risk of non-routine discharge, 6%, for those diagnosed with an HRI and respiratory disease.

3.4. Discussion

This study investigated whether patients hospitalized for HRI and common comorbidities had an increased risk for greater negative outcomes. Although most of the multivariable analyses did not show greater negative outcomes compared to non-HRI hospitalizations the stratified analyses indicated that certain groups had significantly increased negative outcomes for hospitalizations due to HRIs and common comorbidities. The stratified analysis was important because prior research supported conclusions that specific vulnerable groups, such as children, had increased negative health outcomes due to heat-related illnesses.[20,21] By using a stratified analysis population denominators represented populations and were more reflective of previous studies' conclusions identifying vulnerable populations with the identified underlying medical conditions. Children, aged 0-17 years, were particularly vulnerable showing increased risk of death and nonroutine discharges for HRIs alone and with additional diagnoses of renal and respiratory diseases. Risk of death among children with a respiratory disease and HRI diagnosis was greater than 6 times that of children with only a respiratory disease diagnosis, without the co-diagnosis of HRI. Children also showed increased number of procedures among diagnoses of diabetes and respiratory diseases with a heat-related illness diagnosis. While children have been noted as particularly vulnerable to high temperatures the current study also highlights a number of significant findings indicating that common comorbidities play a role in further defining which groups of children are at a heightened risk for negative health outcomes due to heat-related illnesses. A recent meta-analysis on the impact of temperature on children's health argued that more research is needed to identify possible modifiers of temperature and its relationship with children's health which is highlighted in the results of this study and asserts the need for further research in this area.[22]

As with children, the elderly are considered at an increased risk of mortality and morbidity due to heat-related illnesses. Though in the current study increased risk of death was seen among age groups 0-64 years old for HRI diagnoses alone and cardiac diseases with a HRI diagnosis as well as with all age groups for respiratory diseases and a HRI diagnosis based on the stratified analyses. The older age groups were not indicative of greater negative outcomes as readily as other age groups in this analysis. This research highlights that underlying medical conditions play a significant role in morbidity and mortality of HRIs among all age groups, not necessarily just children and the elderly. Males also had increased risk of death with diagnosis of cardiac and respiratory diseases with a HRI, though females had a higher risk of non-routine discharge for a diagnosis of respiratory and renal diseases and HRIs.

Overall, in the current study, increased risks of negative health outcomes were more prominent than increased hospital resource use. Increased length of stay was only seen in Black patients diagnosed with a respiratory disease and a HRI while increased costs and number of procedures were also limited to patients with diagnoses of respiratory diseases and a HRI. Although this study did not control for air pollution, previous studies have suggested a synergistic effect between high ambient temperatures and air pollution on morbidity and mortality.[23,24] This can account for the elevated negative outcomes for patients diagnosed with a respiratory diseases and HRIs. Additionally, patients in urban areas had increased risk of death and non-routine discharges for diagnoses of respiratory diseases with an HRI which could also indicate that air pollution in urban areas is a contributing factor to negative health outcomes of hospitalizations due to heat-related illnesses. In conjunction with the known urban heat island effect, individuals in urban areas with underlying medical conditions, particularly respiratory diseases may have compounded risk of hospitalizations for HRIs and more specific interventions will be needed for this vulnerable population compared to smaller urban and rural populations.

Outcomes from heat-related illness diagnoses can range from mild dehydration, due to electrolyte imbalance, to multi-organ failure in patients presenting with heat stroke. Outcomes are directly related to the hospital resource use and costs associated with the diagnoses of heatrelated illness, usually increasing the length of stay and number of procedures performed as well as having an elevated risk of disability and death. Studies have shown that those individuals presenting with the more severe cases of heat-related illness have a greater need for hospital resources and are at a higher risk for negative health outcomes.[25,26] Some researchers have indicated that individuals that die in heat waves are part of a "harvesting" effect in which heat deaths occur in frail or sick individuals whose death was only hastened by the heat and would have subsequently died within a short period had the heat wave not occurred.[27,28] Though other studies suggest that assessing a harvesting effect is complicated due to multiple subsequent heat events and instances where no harvesting effect was detected for short-term follow-up of heat waves.[29,30] Further research is needed to understand the degree of mortality displacement during extreme heat events.

As this study has shown, there are a range of outcomes of hospitalizations for heat-related illnesses and common comorbidities. Increased costs, hospital resources and negative health outcomes will continue to rise as the intensity and frequency of extreme heat events increase. Studies have shown that heat-related illnesses can damage organs and potentially increase an individual's chance of being susceptible to additional heat-related illnesses from future events.[31,32] Understanding the interaction of underlying medical conditions such as diabetes, cardiac, renal, and respiratory diseases is an important indication of whether an individual is both at risk for a heat-related illness and at an increased risk for greater negative health outcomes from hospitalizations. In the conceptual framework for vulnerability assessment (Figure 3.1) potential outcomes are influenced by sociodemographic and environmental characteristics. Understanding

how underlying medical conditions that are exacerbated by extreme heat events contribute to hospitalizations can help reduce the severity and number of hospitalizations due to heat-related illness.

Heat-illness awareness needs be increased among populations with underlying medical conditions. Informational interventions can be included in preventative care programs similar to that for patients with heart disease and diabetes. Conditions that require consistent monitoring which also put these individuals at increased risk for a heat-related illness can improve outcomes if knowledge and understanding of outcomes is related to these vulnerable populations. In addition, health care professionals need to be further trained to diagnosis and treat patients with medical conditions exacerbated by high ambient temperatures. This includes nurses and physicians, but as more and more people seek information online and at retail pharmacies, information concerning the interaction of extreme heat, underlying medical conditions and heatrelated illnesses will need to include secondary and tertiary sources of medical and health information. Heat-related illnesses are potentially greatly underreported and may lead to wrong diagnoses and treatment of illnesses during heat events. Policies regarding educational information for the underlying medical conditions exacerbated by extreme heat will need to increase the level of knowledge among health care professionals in addition to the at risk populations themselves to achieve a broad spectrum of knowledge within society. Although this study is the first to assess nationally representative data on HRI and common comorbidity outcomes, there are limitations. Administrative data is not as accurate as clinical data and HRIs are almost certainly under-coded and diagnoses of exacerbated medical conditions may take precedence over the underlying HRI. In some instances data analysis was limited due to small sample sizes which reduced statistical significance. Air pollution was discussed as a possible confounder or effect modifier though was not accounted for in the analysis though most studies

have found that heat-mortality and morbidity persist even after adjustments. There were a number of strengths to the study as well. Using the NIS as a nationally representative sample of hospitalizations for heat-related illnesses and common comorbidities and applying sample weights allows for the identification of risk factors and outcomes that are generalizable to a much larger population than the sample size. This contributes to the expanding descriptive data and general understanding of heat morbidity and common comorbidities. And while the fully adjusted model analyses for hospitalizations of HRI and common comorbidities did not show increased negative outcomes, stratified analyses showed increased negative outcomes among specific groups hospitalized and indicated which population with underlying medical conditions may be particularly vulnerable to heat events.

In summary, outcomes of individuals hospitalized for heat-related illnesses and common comorbidities differ from those patients with non-HRI hospitalizations. Elevated risk of negative health outcomes and increased hospital resource use was seen in the stratified analysis of patients diagnosed with common comorbidities, in particular those with cardiac and respiratory diseases with HRIs. This study may help increase knowledge among policy makers and clinicians and target interventions among at-risk populations who are vulnerable due to underlying medical conditions.

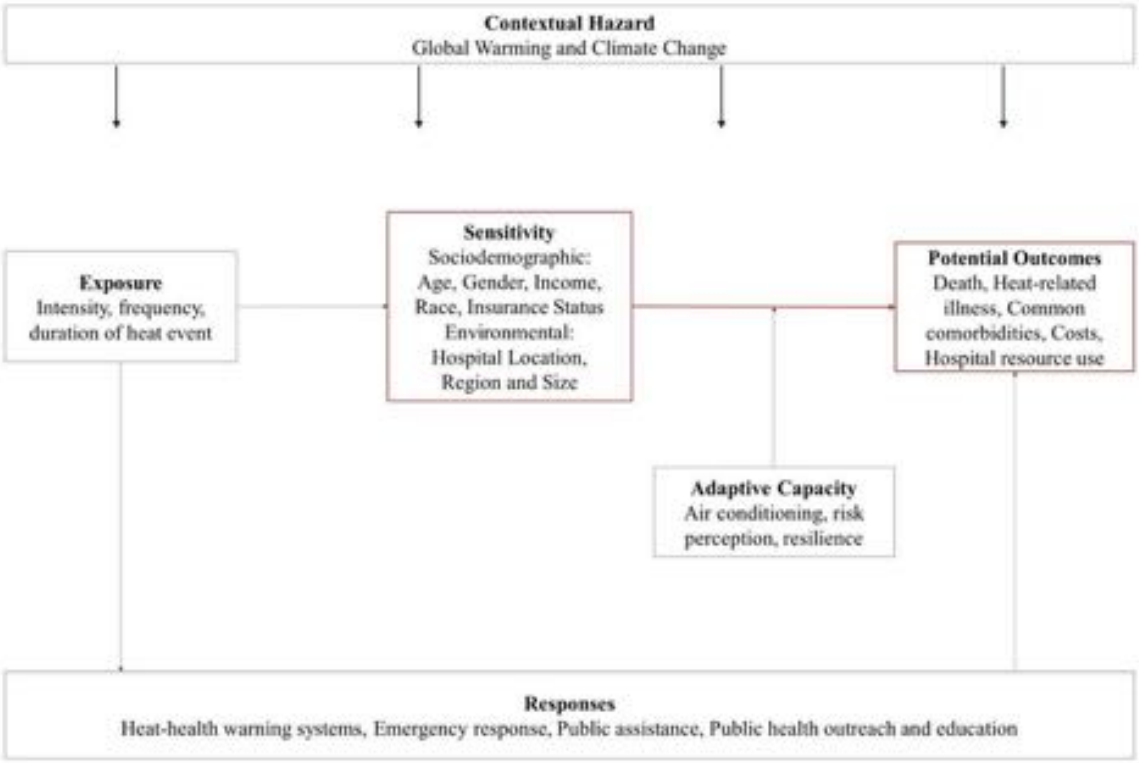

Figure 3.1. Potential outcomes associated with hospitalizations of heat-related illnesses. Common comorbidities along with individual and environmental risk factors associated with heat-related illness diagnoses are analyzed to further elucidate whether populations with underlying medical conditions have greater negative outcomes compared to those without a heat-related illness.

Chapter 4. Association of heat-related illness morbidity patterns and costs related to heatrelated illness hospitalizations

4.1. Introduction

Assessing the impact of climate change on human health and the economy is an enormous task.[1,2] These health impacts will greatly increase economic costs, such as health care expenditures and implementation of adaptive measures, both in preparing for and recovering from hazards related to climate change.[3] Recent studies on the economic cost of climate change have focused on emission rates of greenhouse gases, particularly carbon dioxide, and the impact they will have on global warming. Such studies have been on the estimated cost of reducing our use of fossil fuels and on the implementing carbon taxes but there have been few estimates on the actual economic burden to public health attributed to climate change.[4-6] Previous studies on climate change and health have estimated costs associated for malnutrition, waterborne disease, and malaria[7-9] though little research has been done to estimate the costs of heat morbidity and mortality.

Understanding how heat waves affect morbidity and mortality will be an important factor in how climate change will impact human health in future heat events. Current research has already shown that mortality and morbidity increase during extreme heat events.[10-12] For example, Basu et al. (2012), observed a 393% increase in heat illness hospitalizations, a 3% increase in ischemic stroke hospitalizations and a 15% increase in acute renal failure hospitalizations for every 10F increase in temperature above the mean ambient temperature in a study from California.[13] Studies also predict that there will be an increase in mortality and morbidity from heat-related illnesses from future extreme heat events. Knowlton et al. estimated premature

mortality from extreme heat events in the New York City region to increase by 47% to 95% by mid-21st century compared with the 1990's.[14] As heat events increase, deaths and hospitalizations due to heatrelated illnesses will continue to incur greater economic costs. Only a handful of studies have either identified or estimated costs associated with high ambient temperatures and extreme heat events.[15-17] Knowlton et al. identified total health costs associated with a 2006 California heat wave to be $5.4 billion, though a significant portion of the estimated case was due to premature death ($5.1 billion).[16] Interventions such as heat-health warning systems (HHWS) and air conditioner use have proven effective in reducing heat morbidity and mortality though there is a gap in the research providing cost-effective and cost benefit analyses for policymakers to implement strategies for reducing heat mortality and morbidity.[18] By examining the conceptual framework (Figure 4.1), hospitalization costs are indirectly influenced by society's adaptive capacities. Responses to an extreme heat events and how those responses directly relate to potential outcomes provide information on cost benefit analyses of interventions used to prevent heat-related illness hospitalizations. By exploring these two facets within the vulnerability assessment framework and examining how adaptive capacities and responses impact heat-related illness hospitalization costs, this research will yield additional information to on the economic burden of heat morbidity. The goal of the current study then is to calculate the cost of hospitalizations due to heat-related illnesses in the United States from 2001 to 2010. Although there are a number of different projections and scenarios for the future climate, all estimate an increase in ambient temperatures and extreme heat events. This study will also aim to estimate the future cost of hospitalizations due to heat-related illnesses based on projections from a number of these studies. Additionally this study will briefly look at air

conditioning use and cost in 2009 as a potential cost-effective strategy to combat heat morbidity. Because there is a limited amount of information regarding the economic cost of heat-related morbidity and mortality, this study will be important for examining the costs of public health preparedness and responses to climate change and extreme heat events.

4.2. Methods

4.2.1. Data Sources

The primary source of data for this study was the 2001 to 2010 Healthcare Cost and Utilization Project (HCUP) Nationwide Inpatient Sample (NIS), which was developed by the Agency for Healthcare Research and Quality (AHRQ). The NIS is the largest all-payer care database, with data from approximately 8 million hospitalizations per year (about 20% of all hospital discharges in the United States). (HCUP) The NIS includes data on patient demographics and hospital characteristics, primary and secondary diagnoses coded according to the *International Classification of Diseases, Ninth Revision* (ICD-9) (with up to 15 diagnoses available for the years 2001-2008 and up to 25 diagnoses for 2009-2010), primary and secondary procedures (ICD-9 coding up to 15 diagnoses available for the years 2001-2008 and up to 25 diagnoses for 2009-2010), type and source of admission, discharge disposition, primary payer type, total hospital charges, and length of stay. Stratification and weighting variables allow calculation of national estimates and account for the complex sampling design.[19,20]

Data on air conditioner use and cost was derived from the Residential Energy Consumption Survey (RECS), a national household survey conducted by the United States Energy Information Administration (EIA). In 2009 surveys were collected from approximately 12,000 households,

which were nationally representative of the 110 million residential U.S. households. The variables from the RECS used in this study include census region, state and average air conditioner cost per household.[21]

4.2.2. Subjects and Definitions

The study population for HRI consists of patients in the 2001-2010 NIS with at least one diagnosis of a heat-related illness (ICD-9 codes 992.0 – 992.9) from 2001 to 2010. The main outcome assessed in this study was total billed charges for hospitalization. Total billed charges were converted to individual hospital all-payer inpatient costs by applying the AHRQ hospitalspecific cost-to-charge ratios to total charges within the NIS dataset. Individual patient records were matched by hospital identification numbers and linked to AHRQ hospital-specific cost-tocharge ratios. For hospitals without a listed all-payer inpatient cost-to-charge ratio a group average all payer-inpatient cost was used. Some years, records for hospitals in Texas, Pennsylvania and Hawaii did not include either cost-to-charge ratios. For these hospitals the group average all payer-inpatient cost was substituted with a cost-to-charge ratio from hospitals in the same census region matched on hospital location and bed size.

4.2.3. Statistical Analysis

Descriptive statistics were used to report hospitalization numbers, aggregate costs, mean costs, standard deviations (SD±) and median costs. All analyses were weighted to obtain national estimates and yearly costs were adjusted to 2013 US dollars accounting for inflation, using the medical consumer price index. Estimated costs of hospitalizations due to heat-related illnesses of future events were based on analyses of studies using climatic models predicting an increase in

the intensity and frequency of extreme heat events. Studies by Wu, et al., Gao, et al., and Lau, et al. indicate at least a 2-fold increase but possibly as high as a 7-fold increase by mid-to-late century for the number of extreme heat events per year compared to recent years.[22-24] The current analysis includes a 50%, 2-fold, 5-fold and 7-fold increase to the 2010 aggregate costs of heatrelated illness hospitalizations which represents estimated costs of hospitalization for predicted events occurring mid-21st century.

All statistical analyses were performed using SAS 9.3. This study was approved by the Institutional Review Board of Hunter College and conforms to the HCUP data use agreement.

4.3. Results

4.3.1. Costs of heat-related illness hospitalizations

Table 4.1. shows the actual aggregated, mean and median costs of hospitalizations due to heatrelated illnesses from 2001 to 2010. As the number of cases increase over the time period, the inpatient costs also increase (all costs in US Dollars). A low of $30.1 million is seen in 2004 and a high of $81.5 million in 2010. The average cost for the ten year period is about $52.7 million while the total aggregate cost for the time period is just over half a billion dollars ($542.7 million). Mean and median adjusted costs remain similar over the 10 year period, though both increase in 2010, due to the high number of total cases in that year compared to previous years.

4.3.1. Estimated costs of heat-related illness hospitalizations

Estimated costs for future heat events were based on the 2010 aggregated costs of heat-related illness hospitalizations and are shown in table 4. 2. A 50%, 2-fold, 5-fold and 7-fold increase in

the number of heat-related illness hospitalization costs was calculated. These resulted in estimates close to and above half a billion US dollars for a 5-fold ($407.5 million) and 7-fold ($570.5 million) increase based on current costs of hospitalizations for heat-related illnesses annually. Moderate increases were seen in the 50% and 2-fold estimated costs, at $122.3 million and $163 million per year.

4.3.1. Costs of air conditioner use in the United States, 2009

Table 4.3. gives the total and air conditioning energy expenditures for all homes in the United States in 2009 as well as the total average energy cost and average energy cost of air conditioning. Average energy cost for air conditioning in the United States in 2009 was $196 per household. Higher averages were seen in new homes in the South and West, while older homes in the Northeast and Mid-West had below average costs for air conditioning.

4.4. Discussion

According to the results, hospital all-payer inpatient costs due to HRI have risen over the time period 2001-2010. Additionally, estimates show that based on projections from climate scenarios where global temperature continue to rise and heat waves become more frequent and intense, the economic cost from hospitalizations due to heat-related illness will also increase by mid-century. The estimated costs which are based on a number of studies that take into account various climate models and a range of possible scenarios.[22-24] These scenarios include the Special Report on Emission Scenarios (SRES) which is used by the Intergovernmental Panel on Climate Change (IPCC) to describe greenhouse gas emission projections of possible future climate change and the Representative Concentration Pathways (RCPs) which greenhouse gas

concentration trajectories used to model possible climate futures.[25] In some cases adaptation and low carbon emission rates account for the lower end estimates while the upper end estimates are largely due to carbon emission rates that will remain similar to today's rates or increase in greenhouse gas emissions, allowing for greater warming of the climate.

Climate models have relied on these projections of greenhouse gas emissions and concentration trajectories to determine rates of global warming and predictions on what temperatures will be in our future climate.[26] Because of this most of the cost analyses concerning global warming and climate change have been on how to mitigate or reduce greenhouse gas emissions.[5,27]

Additionally, even if all greenhouse gas emissions were stopped, these gases tend to stay in the atmosphere for long periods of time and concentrations would continue to rise and stay elevated for hundreds of years.[28] Little is known on the economic costs and the costs and benefits of adaptive measures to protect human health from climate change outside of reducing greenhouse gas emissions. Current global knowledge on these economic impacts is generally of low quality and of limited relevance to policy makers concerned with protecting health.[29] Because there is limited quality information available on costs associated with climate change and health, health will need to be an important component in current and future climate change adaptation, especially those related to economic impacts.

The recent United States National Climate Assessment (NCA) included key messages concerning climate change and health; *a*) Climate change threatens human health, and those impacts are already underway in the United States; *b*) climate change will amplify existing nationwide health threats, especially for vulnerable communities; and *c*) preparedness and prevention can protect people from some of these threats, but given that national capacity to

adapt to increasing threats may be limited in the future, early, preemptive action has the most impact potential.[30] Despite the risks and recent priorities to include the impact of climate change on health as a focus for research and policy, funding has been insufficient.[31] It has also been stated that the effects of climate change will be felt greatest in populations already at a disadvantage and hence are most vulnerable, including residents of developing countries, elderly, minorities and those of lower socioeconomic status. Climate change has the potential to exacerbate the cycle of poverty and vulnerability if improvements to adaptation methods are not undertaken among these at risk population. Investment in preparedness, awareness and mitigation can help in terms of both inequality and health.[32]

However, studies that assess the effectiveness and cost-effectiveness of interventions to protect health from climate change have also been limited.[33] Heat-health warning systems (HHWS), which are plans that alert and advise populations to mitigate the dangers of heat from high ambient temperatures and heat waves, have been established to some degree though only a small number of studies provide the evaluation needed to prove effectiveness in terms of reaching target populations and reducing adverse health effects.[34] While some studies provide evidence that HHWS are effective[35,36] there has only been one peer-reviewed article to date that has evaluated the cost-effectiveness of such a system.[37] Ebi et al. estimated that the cost of a HHWS in Philadelphia at approximately $210,000 over a 3-year period while the net benefits were around $486 million for 112 lives saved (benefits were calculated using the Environmental Protection Agency's value of a statistical life).[37] Additional cost estimates for HHWS have come from state or municipal reports; one from California indicates that it would cost around $570,000 to develop a statewide warning system and a similar estimate for intervention during excessive

heat warnings annually.[38] In comparison, hospitalizations for heat-related illnesses in 2010 cost $3.1 million in California and $4.2 million Pennsylvania, according to the data from this study. Additionally, a report on the potential economic cost to the state of New Mexico from climate change indicated that medical care costs of $7 to $45 million would be needed for 'heat waverelated illnesses'.[39] Heat-health warning systems include meteorological data combined with a variety of intervention strategies. Heat health warning systems may appear costly due to the logistics of setting up the system, though medical care and hospitalization costs as shown in this study are greater than the cost of the HHWSs mentioned above. These efforts are a cost effective way for public health officials and municipalities to reduce heat-related illness morbidity and mortality.

In addition, educating the public on personal health protection measures, such as air conditioner use, will be a necessary part of HHWSs. However, even though the use of air conditioning as a protective measure against heat-related illness has proven to be highly beneficial, the increased energy demand during summer months is both a strain on electrical grids and a contributor to increased greenhouse gas emissions.[40,41] When looking at household level air conditioning it can be a cost effective way of reducing heat-related illness hospitalizations, with householders in the United States spending, on average, $196 per year on electrical costs for cooling their homes. Overall cost of energy consumption for air conditioning by state though is in the hundreds of millions of dollars. Problems with electrical infrastructure and resource use argue against the expanding use of air conditioning on the larger scale now and in the future. Though public health officials will need to make difficult decisions about promoting the use of air conditioning among

vulnerable populations in the short-term and sustainability of air conditioning use in the long term using fuel efficient methods with reduced greenhouse gas emissions.

The primary aim of public health is to promptly detect health threats and intervene in a timely manner. Given the multi-disciplinary nature of climate change and the complexity of activities needed to achieve timely interventions, implementation has been difficult. Additionally, funding for research on the health impacts of climate change has been inadequate and remains focused on carbon emissions and the economic impact carbon taxes and caps on carbon emissions will have on society.[33] Climate change and health is a rapidly growing area of research that will benefit from including studies of the economic costs, cost-effectiveness and cost benefits of the public health burden due to climate change. Cost-effectiveness and cost benefits of interventions to protect health from climate change may also improve responses from policy-makers and politicians in directing funds for further research.

In summary, these data show the substantial cost associated with hospitalizations due to heatrelated illnesses and projected estimates for the cost of these hospitalizations in the future climate. The estimates are conservative and represent the absolute minimum cost associated with hospitalizations due to heat-related illnesses, because HRIs themselves are largely underreported with underlying medical conditions, such as cardiac and respiratory diseases, taking precedence as the primary diagnosis for hospitalizations during heat events. While known interventions such as air conditioner use may be beneficial in the short term, more information regarding the cost benefits of additional interventions are needed. Heat-health warning systems have been shown to be a cost-effective intervention, though little evaluation has been done both in terms of economic and health benefits. These intervention strategies are needed to substantiate the evidence needed to both show economic effectiveness and secure funding and research focus on climate change

and health. By examining the costs associated with hospitalizations of heat-related illnesses we have initiated some of the first steps in identifying economic factors that influence the impact of climate change on health.

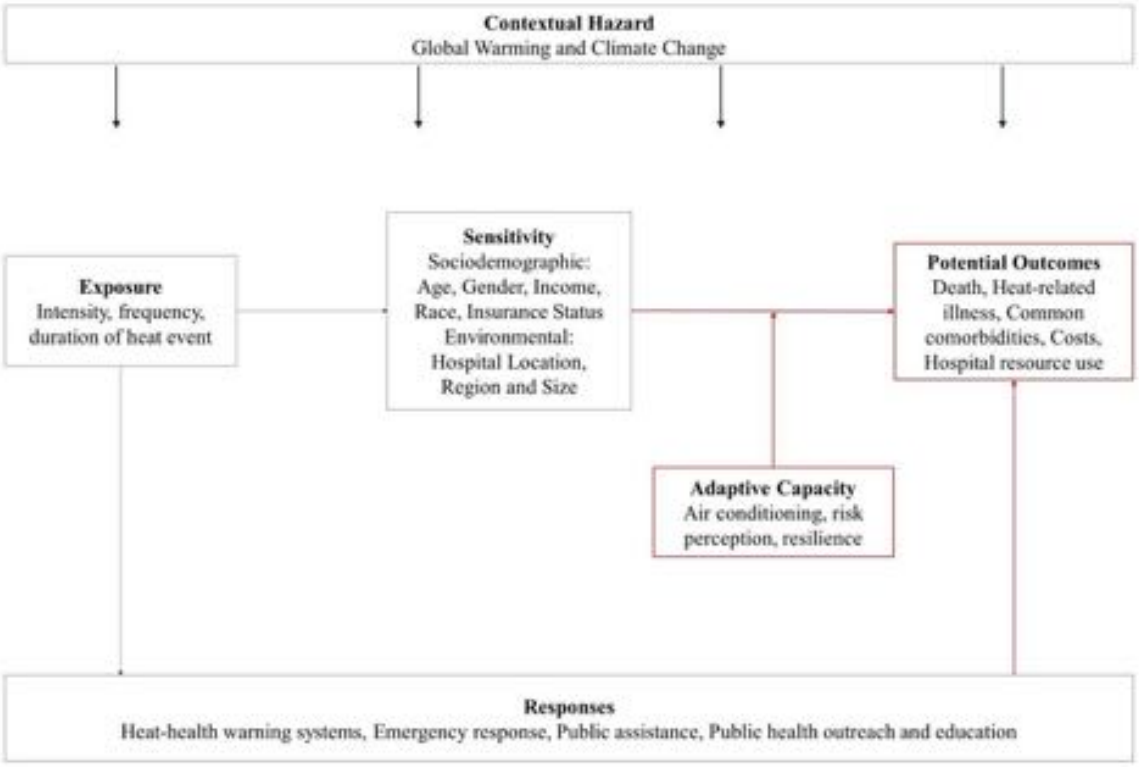

Figure 4.1. Explores costs associated with hospitalizations of heat-related illnesses. As heat-related illness hospitalizations increase with increasing frequency of extreme heat events, costs will continue to rise. Hospitalization costs are compared to the costs of air conditioning and established heat-health warning systems to determine cost-effectiveness of current intervention strategies.

Chapter 5. Discussion

5.1. Overview of the dissertation

This cross-sectional study of hospitalizations in the United States due to heat-related illnesses aimed to expand the limited knowledge of the risk factors, outcomes and costs associated with heat morbidity. First, risk factors were identified by comparing all heat-related illness (HRI) hospitalizations over a 10-year time period during the summer months with all other causes of hospitalizations to highlight demographic and environmental characteristics associated with hospitalizations due to HRIs. The study then examined outcomes among common comorbidities (diabetes, cardiac, respiratory and renal diseases) with and without HRI diagnoses to understand how HRIs may increase the risk of death, discharge status, hospital resource use and costs among these exacerbated medical conditions commonly associated with high ambient temperatures and extreme heat events. The study further focused on the direct costs associated with hospitalizations due to HRI and estimated future costs by examining climate models projecting an increase in ambient temperatures as well as an increase in the frequency and intensity of extreme heat events. The three aims of the study fit within the conceptual framework of a vulnerability assessment diagramed in figure 1.1 examining how exposure to heat events, sensitivity of the populations, outcomes and adaptive capacities are related in identifying risk factors and patterns for hospitalizations of heat-related illnesses. The framework exemplifies the connection of how heat events are associated with heat-related illnesses, but this study then

examines aspects of the framework, as highlighted in figures 2.1, 3.1 and 4.1, identifying individual and environmental characteristics and examining adaptive capacities that influence the potential outcomes of these hospitalizations. Additionally, by examining the costs associated with hospitalizations the study explored the adaptive capacities and responses that may affect these healthcare costs. In the following section, the main findings and interpretations are summarized.

5.2. Summary of the findings

5.2.1. Chapter 2

Analyses of hospitalizations due to heat-related illnesses in the United States, 2001-2010 highlighted a number of risk factors. It is important to distinguish between heat morbidity and heat mortality since risk factors can be significantly different. This study has found that individuals over 40 years old and males were more likely than females to be hospitalized for a HRI. Prior research in heat mortality had indicated that children and the elderly were most at risk. The current research shows that many age groups are at risk for heat-related illnesses and the perception of who is vulnerable may not be well understood by the general population. As global warming increases average ambient temperatures and extreme heat events become more common, populations that were previously thought to not be at risk for HRI may now be included as vulnerable groups.

Another important finding indicated that people in rural areas and small urban clusters were more likely to be hospitalized for HRIs compared to people in urban areas. The urban heat island effect has shown us that higher ambient temperatures are more likely to occur in urban centers due to heat-retaining properties of building and roads; thus, it is assumed that due to these higher

temperatures in urban areas there would be more heat morbidity and mortality. This finding requires additional research as the variables contained in the NIS cannot answer exactly why the risk of hospitalization for HRI is greater in rural and small urban clusters, but highlights the need to understand environmental factors such as geographic location and the built environment which may lead to an increased risk for HRIs. While these results are contrary the above mentioned concept the "urban heat island" differences in occupational exposures and air conditioning availability may reflect these differences though the lack of exposure data complicate the interpretation of these results.

Similar to heat mortality, the current research found that poor populations and those identified as Black, Hispanic, Asian/Pacific Islander and Native Americans were also at an increased risk of hospitalization due to HRIs. This compliments the spatial analysis conducted for air conditioner use, a significant protective factor against HRI, showing that as air conditioner use in the United States grew from 2005-2009, populations at greatest risk, elderly and low-income families had a decrease use of air conditioners. While air conditioner use may not be the best alternative due to its increased energy demand in summer months, it is an option public health officials must consider when trying to protect vulnerable populations from HRIs.

Overall identification of heat-related illnesses is important in understanding who is most at risk and informs our ability to target these populations for protective interventions. In this analysis a decreased risk of diagnosed common comorbidities with heat-related illnesses was contrary to previous research indicating that these common comorbidities are exacerbated during extreme heat events. This is interpreted cautiously as the severity of the underlying condition may have led providers to code these conditions and under-diagnose or under-code HRI. Underreporting of HRI has been noted in past studies as well as the current study and may indicate that greater

knowledge is required among health care professionals in recognizing and diagnosing heatrelated illnesses especially when common comorbidities are presented.[1,2]

5.2.2. Chapter 3

In addition to the risk factors for hospitalization of HRI, outcomes for these hospitalizations can also help us to better understand vulnerable populations to extreme heat events. As noted in Chapter 3, hospitalizations for heat-related illnesses also include common comorbidities such as diabetes, cardiac, renal and respiratory diseases. These underlying medical conditions may be exacerbated due to heat events and subsequent heat-illnesses triggering a hospitalization. The current research did not see any increased negative health outcomes (death or non-routine discharge) or increased hospital resource use (length of stay, number of procedures or total charges) among those hospitalized with a heat-related illness and those hospitalized with diabetes, cardiac or renal disease and a concurrent HRI diagnosis. Although those hospitalized with respiratory diseases and a HRI diagnosis did show increased number of procedures as well as increased risk of death and non-routine discharges compared to populations hospitalized with only a respiratory disease.

While multivariable adjusted regressions did not show increased risk of negative health outcomes or increased hospital resource use among those hospitalized for heat-related illness or diabetes, cardiac and renal diseases with a HRI, stratified analysis of sociodemographic and environmental characteristics showed an increase in negative outcomes among certain populations. By changing the population denominator, for example, examining males diagnosed with a respiratory disease compared that to males diagnosed with a respiratory disease and heatrelated illness, the analysis was able to isolate the population of males with a diagnosis of respiratory disease in examining how the effect of a diagnosed heat-related illness impacted

outcomes among that population. For heat-related illnesses alone, increase risk of death was seen among 18-64 year olds, the uninsured and those hospitalized in the Western United States.

Diagnoses of diabetes with a HRI showed increased number of procedures among infants and children as well as an increased risk of non-routine discharges identifying as Asian/Pacific Islander, Native American or Other.

Discharges with a co-diagnosis of a cardiac disease and a heat-related illness showed increased risk of death among many different groups. These include males, persons 18-74 years old, Blacks, Hispanics, hospitalizations in the lowest zip-code income quartile and those who were uninsured. Additionally, those hospitalizations in urban areas and those in the West were also at an increased risk of death from cardiac disease and a HRI diagnosis as compared to those with just a diagnosis of cardiac disease. Limited negative outcomes were seen in those diagnosed with renal diseases and a heat-related illness though increased risk of death was seen among females, infants and children (0-17 years old).

Similar to the multi-variable analysis of respiratory diseases with a HRI diagnosis, the stratified analyses showed a number of increased negative outcomes. Almost all sociodemographic and environmental characteristics showed increased risk of death and non-routine discharges, with infants and children (0-17 years old) having the highest risk (6.5 increased risk of death and 3.3 increased risk of non-routine discharge). Blacks and those aged 18-39 years old showed an increase in negative outcomes for each category analyzed while the uninsured showed significant results for increased negative outcomes in all but two categories (length of stay and total charges). These results give a clear indication that respiratory diseases with a heat-related illness diagnosis play a significant role in the outcomes for hospitalized individuals. Heat-related illnesses may exacerbate other common comorbidities and can significantly impair health

outcomes. The study results from Chapter 3 highlight increased negative outcomes for heatrelated illness in addition to the risk factors described in Chapter 2; combined these indicators

can help researchers better understand the HRI vulnerabilities among specific high risk populations.

5.2.3. Chapter 4

During the study period, 2001 to 2010, hospitalizations of heat-related illnesses increased at a higher rate than all other hospitalizations. Although comparatively costs for heat-related illness hospitalizations were lower than all hospitalizations during this time period, the average inflation-adjusted hospital stay cost in the United States has remained stable over the years, while costs for heat-related illnesses have increased as much as 18% in years corresponding with increased number of heat events.[3]

From 2001 to 2010 the average inflation-adjusted cost for a heat-related illness was $7,505 (all costs represent inflation-adjusted 2013 US Dollars) and total aggregate costs for all hospitalizations were $542.5 million. Aggregate costs of heat-related illness hospitalizations went from $41.5 million in 2001 to $81.5 million in 2010.

Studies using climatic models predict that there will be an increase in frequency and intensity of heat events corresponding to a 2-fold to 7-fold increase by mid-century, the estimates vary due to the modeling of low emission and high emission scenarios.[4,5] The predicted increases in extreme heat events were then used to estimate the potential for costs associated with heat-related illness hospitalizations by mid-century. A 7-fold increase in costs of hospitalizations for heat-related illness (based on 2013 inflation-adjusted costs from 2010 HRI hospitalizations) would be

approximately $570.5 million per year. These estimates indicate that over half a billion dollars per year would be needed to cover costs of heat-related illness hospitalizations by the mid-21st century. The estimates are conservative and represent the absolute minimum cost associated with hospitalizations of heat-related illnesses, due to the conclusions that HRIs themselves are largely underreported as indicated in Chapter 2.

Protective measures such as heat-health warning systems (HHWS) and air conditioning use were examined as cost-effective strategies in reducing heat-related illness hospitalizations. Studies show that HHWSs would cost considerably less to implement and run compared to the cost of individuals hospitalized for HRIs. While there is still some debate about the functionality of these systems, heat health warning systems may be a cost-effective measure to prevent heat-related illness.[6,7]

Additionally, air conditioning use in either residential homes or public cooling centers provides significant protection against HRIs.[8] Analysis of data from the Residential Energy Consumption Survey (2009) estimated that householders in the United States spent $196 annually to cool their homes. This cost is also significantly less than the average cost of a hospitalization due to HRI. While air conditioning may be a protective factor, the demand on energy infrastructure and emissions related to energy use for cooling may be contrary to the concepts of global warming and climate change. Alternative methods to reduce costs for HRI hospitalizations will need to be explored if we continue to see that climatic models and estimated costs increase significantly in the future.

5.3. Limitations

This study has several limitations other than the constraints of a cross-sectional analysis. First, the Nationwide Inpatient Sample (NIS) is an administrative database which limits analyses based on available variables in addition to not being as accurate as clinical data. Additionally ICD-9 codes are prone to coding error and reporting of some variables varies state by state, depending on the reporting requirements for that state.[9] The data in the NIS is based on coding by healthcare providers and confers the prevalence of heat-related illnesses based on their diagnostics criteria; research was not the intended use for this data. Because coding is to facilitate reimbursement and not for epidemiological studies this may introduce selection bias into coding within the heat-related illness spectrum towards that of the more severe cases such as heat stroke. Also, only variables that were included in the NIS dataset were used to control for confounding thus not accounting for variables such as air pollution, which may have an effect on hospitalizations of heat-related illnesses. Second, due to the nature of how data is collected by the NIS, date and time of hospitalization cannot be determined and thus, cannot be linked to a specific heat event. Because of this cases of heat-related illness hospitalizations include both classic non-exertional HRIs and exertional HRIs. This bias, however, may be counterbalanced by controlling for age as most exertional heat-illnesses are seen in healthy and young individuals active primarily outdoors during the summer months. Third, research involving administrative databases may be underreporting chronic comorbidities.[10] Underreporting of heat-related illnesses is also occurring due to underlying medical conditions such as cardiac and respiratory diseases being exacerbated during heat events which in turn may be diagnosed as the primary cause of hospitalization even if exposure to heat was the initial cause. Additionally, due to underreporting of heat-related illnesses, estimations of costs and future costs are conservative and represent the absolute minimum costs associated with hospitalizations of heat-related

illnesses. Fourth, data from the Residential Energy Consumption Survey were not linked to the NIS data due to the different levels of measurement (individual discharge record versus household) thus spatial analysis of air conditioning data can only be made at the ecological level, limiting generalizability due to the ecological fallacy.

5.4. Strengths and public health significance

There are a number of strengths in this study. First, by studying heat morbidity, this research adds significantly to the limited knowledge on heat-related illnesses and outcomes that do not relate specifically to heat mortality. By understanding that there are differences in risk factors and outcomes between heat morbidity and heat mortality public health officials can tailor interventions to a broad range of vulnerable populations. Second, using the NIS as a nationally representative sample of hospitalizations for heat-related illnesses and applying sample weights allows for the identification of risk factors and outcomes that are generalizable to a much larger population than the sample size. This contributes to the expanding descriptive data and general understanding of heat-related morbidity in a public health context. In particular, the use of hierarchical modeling in identifying risk factors through hospitalizations accounts for the interacting effects of patient and hospital characteristics. This information will improve the overall knowledge of public health researchers using vulnerability assessments in understanding both individual and environmental characteristics that influence risk factors for heat-related illnesses. Third, while regression analysis on all hospitalizations did not show increased negative outcomes, stratified analyses showed increased negative outcomes among specific groups hospitalized with a HRI and common comorbidity. Methodologically, the use of stratified analyses on outcomes of hospitalizations with a diagnosed HRI and common comorbidity provide a more in-depth view of vulnerable populations to HRIs. Since most pathways from climate change to health are complex, this research highlights potential exposure-response

associations in the causal paths which can inform future epidemiological models and studies to further analyze risk factors and outcomes associated with HRIs.[11] Lastly, analyzing costs of hospitalizations from HRIs and estimated future costs provide information on the economic outcomes climate change is has on health. Prior analyses have been limited to economic costs associated with emission though as climate change continues to impact health, costs associated with the disease burden will help garner funding for research to understand the links between climate change and adverse health effects as well as improve adaptation and resiliency strategies to protect vulnerable populations. The negative health effects associated with heat events can be reduced by adequately planned and funded public health responses, this research will assist in improving the cost-effective and cost benefit analyses needed by policymakers and stakeholders to sufficiently allocate resources.[12]

5.5. Policy recommendations and future research directions

This study provides important evidence on risk factors and outcomes associated with hospitalizations due to heat-related illnesses. In general, individuals hospitalized for heat-related illnesses had risk factors that include minorities and persons of lower socioeconomic status, males, most age groups, rural and small urban populations and diagnoses of common comorbidities such as diabetes, cardiac, renal and respiratory diseases. Outcomes of hospitalizations also indicated that as heat events increase the number and cost of hospitalizations will also increase. These study findings justify allocating more resources to target populations at risk for hospitalization due to heat-related illnesses. To achieve this, it will be important to clearly define heat waves, warnings and watches. Currently the National Weather Service (NWS) provides national general heat alert criteria and encourages local NWS Forecast Offices to develop local criteria in cooperation with local emergency and health

officials, and/or utilize detailed heat/health warning systems based on scientific research (JG Ferrell – NWS, personal communication, March 20, 2013). This allows for a wide variety of definitions by local areas which may not be consistent with current scientific research. Implementing more structured protocols for identifying a heat event allows national and local weather services to potentially alert vulnerable populations more rapidly and allows researchers to compare regions of similar climates to further understand heat morbidity and heat mortality patterns.

Along with definitions of heat waves and warnings, definitions of heat morbidity and heat mortality have been imprecise and underdiagnosed.[13] The most recent example of improvements to heat mortality definitions came after the 1995 heat wave in Chicago after many deceased were found at home.[14] As noted in this study, common comorbidities may take precedence over the diagnosis of heat-related illnesses, especially in cases of cardiac or respiratory distress. Educating healthcare professionals and improving the diagnostic procedures for identifying a heat-related illness will improve reporting and further our understanding of heat morbidity. Educating the public will also be an important step in reducing the number of hospitalizations of heat-related illnesses. While many individuals understand broad concepts concerning climate change, consequences of climate change in the general population are less well established.[15] Promoting policies of education and information when experiences of heat waves and heatrelated illnesses are more prevalent, right before summer and during the summer months may garner increased understanding of the impact of climate change on public health, particularly heat wave awareness and improved health outcomes and reduced hospitalizations of heat-related illnesses. The findings in this study indicate a large burden of heat-related illness on working-age populations may be related to occupational exposures. While the Occupational Safety and Health Administration (OSHA) does not have a regulation specifically for heat stress, they have

guidelines that address issues of environmental and occupational exposure to high heat for the workplace. Preventative measures should continue to target at risk workers.

These interventions and adaptations can be leveraged by already existing public health programs.[16] People with chronic medical conditions who regularly receive care can receive additional information about their risk for HRIs during doctor or hospital visits. Also programs that target lower socioeconomic populations can also be used to disseminate information about the risks associated with heat-related illnesses and protective factors such as using air conditioning or visiting a public cooling center. Financial constraints can limit the development and implementation of preventative measures for improving health outcomes associated with extreme heat events. Providing adequate funding in addition to designating project leaders and long term goals to improve heat health awareness will be needed at multiple levels of government and buy-in from stakeholders in the community. Establishing these systems can help plan for and maintain adequate heat-health prevention programs.

As highlighted in this study, the analysis of large administrative data can be useful in further identifying potential risk factors and vulnerabilities for heat-related illnesses. The use of epidemiological methods and data collection from a variety of sources can link known vulnerabilities and protective factors to individual health outcomes to obtain a better understanding of populations most effected by climate change.[11] The lack of high quality longterm data sets reduces our ability to respond effectively to public health emergencies. Improved data collection and analyses in this way will help researchers and public health officials collect relevant and useful information to target interventions towards these vulnerable populations and improve the adaptive capacity and response to extreme heat events.

In conclusion, the study revealed a number of risk factors and negative health outcomes associated with hospitalizations of heat-related illnesses. This study also highlights some of the

economic costs of climate change and provides information on the cost-effectiveness and costbenefit to implementing adaptive measures to prevent hospitalizations of HRIs. These findings provide additional scientific evidence that heat-related illnesses will continue to rise and will continue to be a public health burden as climate changes increase in frequency and intensity of extreme weather events. Along with educational interventions, efforts to understand patterns of hospitalizations of heat-related illnesses will be important to reduce the risk of adverse health conditions and negative health outcomes. This study calls for further research efforts that should focus on improving syndromic surveillance during heat events, clarifying appropriate heat health warning messages and providing stronger theoretical frameworks for projecting heat-related morbidity and mortality.

Appendix I. Demographic Characteristics: Heat-Related Illness (HRI), Diabetes, Cardiac disease Patients, with and w/o HRI diagnosis, 2001-2010 (Summer)

	HRI Hospitalization	Diabetes Hospitalization	HRI + Diabetes Hospitalization	Cardiac Disease Hospitalization	HRI + Cardiac Disease Hospitalization

Abstract

The revolving door pattern of jail incarceration and homelessness and its influence on mortality and morbidity among New York City adults

by

Adviser: Professor Lorna E. Thorpe

Objectives

The purpose of this dissertation study was to identify timing and sequencing of jail incarceration and homelessness by utilizing sequence analysis and to test whether a particular trajectory contributes to mortality risk and discontinuity of HIV care.

Methods

The main data source was an existing matched dataset, constructed using administrative data from the New York City (NYC) Departments of Health and Mental Hygiene, Correction, and Homeless Services. The study cohort consisted of 15,620 NYC adults with recent histories of both jail incarceration and homelessness. Monthly experiences of jail incarceration, homelessness, and community-dwelling in 2001-03 were summarized into trajectory groups using sequence analysis. Then, the study examined associations between trajectory groups and all-cause, drug-related, and HIV mortality risk during the subsequent two years using Standardized Mortality Ratio (SMR) and marginal structural modeling. The study further focused on the sub-set of the cohort living with HIV/AIDS, and tested whether trajectory groups were associated with retention in HIV care and viral suppression.

Results

Sequence analysis identified six trajectory groups of incarceration/homelessness. A majority of the study cohort had sporadic experiences of brief incarceration and shelter stays (**Temporary** pattern), whereas the others had mixed experiences in various lengths and frequencies. The SMR analysis found that all-cause, drug-related, and HIV mortality risk among individuals with the **Temporary** pattern was significantly higher than that of non-incarcerated/non-sheltered NYC adults of the same age, sex, race/ethnicity, and neighborhood poverty. Similarly, after accounting for confounding in marginal structural modeling, the elevated mortality risk was associated with the **Temporary** versus persistent shelter stay patterns (**Continuously homeless** pattern). Of 1,173 individuals living with HIV/AIDS, the **Temporary** pattern was independent of retention in HIV care, but significantly associated with lower prevalence of viral suppression, compared with a pattern of prolonged shelter-free and jail-free period (**Decreasingly homeless** pattern).

Conclusions

Sporadic experiences of brief jail incarceration and homelessness among NYC incarcerated/sheltered adults were associated with excess risk of mortality and low prevalence of viral suppression. The study highlights the importance of public health efforts to modify patterns of incarceration/homelessness experiences, along with behavioral interventions, in order to reduce risk of adverse health conditions.

Acknowledgements

The whole process of the dissertation research is such a humbling experience for me, and I would like to thank Lord for generously providing strength and wisdom in every challenge that I have encountered throughout this intellectual journey. It reminds me that He is the reason and foundation of my existence. Soli Deo gloria!

I am privileged to have renowned epidemiologists in my committee members. My advisor, Dr. Lorna Thorpe, is a great role model. Her energy and passion for public health is such an inspiration for me. I am particularly grateful for her to be able to make time to meet with me despite all her responsibilities and busy schedules. I also thank you for teaching me how to balance between the big picture and the scientific details when writing a manuscript. I am grateful for Dr. Denis Nash to raise important bias issues, and encourage me to run various sensitivity analyses. As a result, the dissertation findings have been tremendously strengthened. I am also very fortunate to have Dr. Mary Clare Lennon in my committee who introduced sequence analysis to me. She is one of the innovators bridging between quantitative sociology and public health, continuously motivating me to follow her steps. I would like to thank Dr. Tiffany Harris who has taught me how to write a good scientific paper and, with insightful and timely comments she has helped me transform ideas, paragraphs and, chapters as a unified scientific manuscript. In addition, without her support to authorize the dissertation research as a part of my daily works, it would have been impossible to complete the dissertation according to the proposed time line.

I thank my beloved wife, NAME REDACTED, and two beautiful daughters, NAMES REDACTED. Even though you were in Korea due to family emergencies throughout the whole dissertation research, I felt your love, presence, and support. I love you more than ever! From the beginning of the study, my parents and parents-in-law fully understood why I pursued the doctoral degree and kept supporting me to run to the finish line. I would like to thank friends and families in Korean Bible Study groups and New Frontier Church for their encouragement and prayers.

Lastly, I really appreciate amazing support from my two bosses, NAMES REDACTED and colleagues at New York City Department of Health and Mental Hygiene.

.....98

Chapter 1. Introduction

1.1. The revolving door problem in public health

Jail incarceration and homelessness are strongly correlated in the United States (US), and about 25,000 adults in New York City (NYC) had histories of both events between 2001 and 2005.[1] Homeless individuals may be at high risk of incarceration, as their behaviors related to survival or substance use in public are often criminalized.[2,3] The reverse pathway also is likely. Those released from prison or jail, as opposed to the general population, are more likely to become homeless, as they encounter limited opportunities for employment and housing, and experience social stigma in the community.[4,5] This frequent transition between jail incarceration and homelessness is one particular case of the revolving door phenomenon, which refers to a cyclical pattern of institutional recidivism such as repeated admission to jails, prisons, homeless shelters, and psychiatric hospitals.[6] This revolving door problem of incarceration and homelessness is considered a serious public policy failure and human rights crisis, draining public resources while letting a particular group of people cycle through shelters and correctional facilities. It also has serious public health ramifications. A limited body of studies has shown that people with histories of both incarceration and homelessness are at greater risk of morbidity and mortality compared with those experiencing only one event.[1,7] For example, a recent NYC longitudinal study found that formerly-incarcerated people with histories of homelessness were more likely to die from drug-related causes and suicide than formerly-incarcerated people who did not have histories of homelessness.[1] This excess risk of mortality and morbidity may be the result of particular recent or longstanding behaviors such as criminal histories or substance use, lifecourse

exposures related to poverty, severe mental illness, or circumstances such as unemployment.[8] Alternatively, the excess health burden potentially reflects the cumulative or incremental effects from transitions in and out of these institutions and states of being, affecting stress and potentially introducing barriers to stable health care. Both perspectives may be equally important in understanding potential causal mechanism by which homelessness and incarceration could influence health conditions.

Despite the institutional similarities between sheltered homelessness and incarceration (e.g., residential facilities operated by public agencies), the often cyclical nature of exposure, and the sizable overlap between the two populations, researchers typically consider each event separately, resulting in two separate bodies of literature. This may be because the former is influenced by housing status and policies, whereas the latter is based on a determination that a criminal justice law has been infringed upon. In order to describe the background of the revolving door phenomenon of incarceration and homelessness ("the revolving door problem") in a public health context, the dissertation first reviews existing evidence on the separate linkages between homelessness and health and incarceration and health. It then summarizes common empirical and theoretical grounds for these associations.

1.2. Homelessness and health

Homelessness refers to a condition where individuals or families do not have a fixed and regular nighttime residence.[9] It is considered as an extreme case of housing instability, and about 26 million adults in the US (14% of the US adult population) have reported at least one homeless experience.[10] It is well established in the current literature that poor health conditions are associated with homelessness. About 39% of homeless adults in the US have been found to have

current mental illness, which is higher than the national estimate of 25% of adults.[11,12] In particular, about 50% of a national sample of US homeless adults reported current drug and alcohol problems.[11] Homeless adults also disproportionately suffer from both chronic and infectious diseases. For example, one study identified the prevalence of diabetes and hypertension among 351 NYC homeless adults with an average age of 35 years to be 6.3% and 17.1%, respectively, which was higher than the corresponding prevalence in US adults aged 3544 years (1.9% and 7.4%, respectively).[13] A recent meta-analysis of 43 studies from various countries indicated that the prevalence of tuberculosis (TB) disease and hepatitis C virus infection is also higher among homeless people compared with the general population.[14]

Consistent with poor mental and physical health conditions, excess mortality risk is evident among homeless adults. In a NYC retrospective cohort study, being in a shelter for at least one night was associated with an elevated risk of drug-related death and suicide.[15] Similarly, the race-adjusted mortality due to drug overdose was almost 16 times higher among homeless men aged 25-44 years in Boston, compared with the general population in Massachusetts.[16] In a United Kingdom study of two retrospective cohorts, homelessness was an independent risk factor for mortality even after controlling for demographic characteristics and clinical conditions.[17]

Along with adverse health conditions, homeless adults disproportionately suffer from limited health care access. A US national cross-sectional study of homeless adults found that almost two thirds reported unmet needs in medical, mental, or dental care in the past year.[18] Their rates of unmet need in specific areas of health care were six to 10 times higher than those in the US population overall.[18] Among adults living with HIV/AIDS, homelessness is associated with a low likelihood of continuity of HIV care (e.g., making at least one visit to primary care doctors

every six months) and initiation of and adherence to antiretroviral regimens.[19,20]

1.3. Incarceration and health

The US criminal justice system operates prisons and jails as places of imprisonment.[21] Prison is run by federal or state governments, and detains convicted individuals who are sentenced for more than one year. Jail is a local government institution that holds individuals charged with less serious crimes and sentenced for a shorter time period than prisoners (maximum one year). Those waiting for trials or who have violated probation and parole may also be detained in jail. In 2011, the point-in-time estimate of adults in the US prisons and jails was 1.6 million, while the total number of adults released from correctional facilities was estimated to be 10 million over one-year period.[22] Similar to homelessness, experiences of incarceration are associated with poor health conditions. Approximately 45% of federal prisoners and 56% of state prisoners in the US have mental illness, which is higher than the national prevalence (25%).[11,23] Consistent with high burden of mental illness, more than 70% of US incarcerated adults have histories of substance use.[4] A study conducted in 2004 found the age-adjusted prevalence of HIV was almost two times higher among a representative sample of US prisoners as opposed to the general noninstitutionalized US population[24] and even greater disparities were found in the prevalence of hepatitis C virus (17-25% vs. 2%) and TB (1% vs. 0.01%).[25] Increased odds of chronic diseases including hypertension, asthma, arthritis, and cancer are also associated with being incarcerated in US prison or jail after adjusting for demographics and alcohol use.[26]

During incarceration, inmates may receive some health care services and screenings (e.g., active screening for sexually transmitted diseases, TB, HIV, and hepatitis C) that are potentially more extensive than what they had access to in the community.[21] Several studies have shown that

among US and Canadian prisoners living with HIV/AIDS who disclose their HIV status, essential antiretroviral treatment and care are initiated in the early incarceration and well maintained until release.[27,28] Yet, screening for diseases and improved HIV care during incarceration may not necessarily mean that inmates generally receive adequate health care in prison or jail. According to the 2004 US national cross-sectional prison and 2002 jail surveys, about 30% (prisoners) and 42% (jail inmates) on prescription medications prior to incarceration reported discontinuing them after being admitted to prison or jail.[24] In addition, some benefits from improved access to care are no longer observed upon release from correctional facilities, as evidenced as a decreased level of antiretroviral treatment adherence or increased viral loads post release.[28,29] It may reflect limited health care access that this population chronically experiences prior to incarceration or life challenges that former inmates encounter in the community such as few opportunities for stable housing and employment. Similar to access to care, all-cause mortality while incarcerated is lower than that among the general population (e.g., Standardized Mortality Ratio = 0.62-0.85),[30,31] but this protective effect of incarceration tends to disappear after release from prison or jail. A recent meta-analysis shows that excess all-cause mortality risk after prison release was consistently observed across seven different prison populations.[32] In particular, Binswanger and colleagues found that the excess mortality risk was the highest during the first two weeks after release among former prisoners in Washington State.[33] They pointed out that the elevated risk of drug-related mortality, cardiovascular disease mortality, suicide, and homicide during the first two weeks post-release were the largest contributors to the excess mortality risk.

1.4. Common explanations about health and homelessness/incarceration

In current research, there are two major hypothesized mechanisms that explain excess risk of morbidity and mortality among homeless or incarcerated adults: an individual risk factor approach and a structural exposure approach. These approaches (described below) provide a common ground for synthesizing separate bodies of the current literature to understand and test risks associated with excess health burden among individuals with both experiences.

1.4.1. Individual risk factor approach. This approach considers homelessness or incarceration as a marker of particular demographic and behavioral characteristics.[34] It postulates that adverse health conditions associated with homelessness or incarceration are due to a high concentration of people with underlying health conditions, limited access to care, or risky behaviors such as active substance use and high-risk sexual behaviors prior to these events.[21] Given substantial overlap in characteristics between the incarcerated and homeless populations, including low socioeconomic status and substance use behaviors, the greater excess health burden among those with both experiences as opposed to those with only one experience or the general population may be a manifestation of a poorer underlying health status rather than a direct causal influence of the incarceration or shelter experience itself. The underlying assumption of this approach is that individual characteristics, risk behaviors, or network factors act as a common set of causes of adverse health conditions and homelessness/incarceration.[34] For example, in the crosssectional study of the convenience sample of homeless adults in San Francisco, the excess rate of HIV infection associated with histories of incarceration was interpreted as an indication of the particular social or personal network factor such as the number of sex partners and substance use that were positively associated with incarceration experiences as well as a risk factor of HIV infection.[7] In the individual risk factor approach, the elevated risk of HIV infection among

homeless adults with incarceration experiences, as opposed to those with homelessness only, was attributed to higher prevalence of risky sexual behaviors and substance use, rather than exposure to incarceration.[7] On the other hand, as an explanation of a protective effect of incarceration on all-cause mortality, incarceration has been considered to be a marker of protective factors based on the assumption that one needs to be physically healthy enough to commit crimes.[35]

1.4.2. Structural exposure approach. In this approach, homelessness and incarceration are considered as a process that damages biological systems and limits stable access to healthpromoting/protecting resources. Unlike the first approach that focuses on a role of demographic and behavioral characteristics or underlying health conditions, it emphasizes describing mechanisms by which the experiences of homelessness and incarceration cumulatively influence health via physiological processes or limited access to care.[34] As seen in recent evidence on the independent effects of homelessness/incarceration on adverse health conditions, this approach points to unique risks beyond demographic and behavioral risk factors such as persistent stress that lead to physical and mental impairment and social/administrative barriers that lead to social disadvantages.[17,36] This perspective has been conceptualized as being composed of three aspects: a psychological process, a physical process, and the influence of health care access.[37] For the psychological aspect it postulates that a lack of a permanent nighttime place or experiencing physical confinement requires a radical adjustment of behaviors that substantially increases stress, which in turn prevents optimal physiological functioning as evidenced in the association between an increased allostatic load due to persistent stress and excess risk of mortality and morbidity.[36,38-40] When it comes to the transition from correctional facilities to communities, the structural exposure approach hypothesizes that former inmates are stigmatized and stressed as

society typically discriminates against these people in economic and social activities.[36,41] Supporting this hypothesis, incarceration has been associated with a high likelihood of psychological stress as well as stress-related diseases.[36] In terms of the physical aspect, homelessness and incarceration are hypothesized to have a negative impact on health via radical changes in living conditions or increased exposure to violence and environmental hazards.[17,36] Evidence also shows that incarceration could decrease drug tolerance levels due to temporary abstinence of drugs during incarceration, increasing the chance of a drug overdose among recently-released prisoners or jail inmates.[1,42] A contrasting view, however, highlights a decreased exposure to physical harm (e.g., traffic accidents, drug overdose) during incarceration, proposing that incarceration has a protective effect on health. This perspective has been supported by studies that reported lower risks of all-cause death during incarceration compared with the general population, mainly driven by lower risk of death due to external causes.[30,31]

In addition to the biologic explanation, homelessness and incarceration are barriers to essential health resources. Homeless people may consider primary care less important than urgent needs for survival (e.g., access to housing, personal hygiene, and food), which leads to disrupted disease management (e.g., HIV and diabetes) and prevention.[12,18] Additionally, distrust in public health systems, social isolation, and discrimination can create non-financial barriers to medical care.[12,18] For incarcerated individuals, there are two conflicting perspectives about the possible association between incarceration and access to care. One posits that incarceration could potentially exert positive health effects because the correctional system can provide essential health care for people with limited access prior to incarceration.[39] In particular, a highly controlled environment in correctional facilities has been considered as an ideal setting to

effectively administer long-term treatments such as antiretroviral treatment to HIV-infected prisoners who disclose their HIV status.[28] A contrasting view interprets a lower mortality risk during incarceration as an artifact that prisoners are protected from violence, drug overdose, or traffic accidents, rather than being due to improved health care access.[30] About 25% of prisoners using prescription drugs prior to incarceration reported that medications were discontinued after prison entry in the 2004 US national survey,[24] providing some evidence against the former perspective. Furthermore, a study from Georgia demonstrates that the protective effect of incarceration on mortality disappeared when compassionate release was accounted for, which represented 27% to 45% deaths among Georgia prisoners in 1991-2006, implying that release of sick prisoners is a probable cause of the decreased mortality rates among people at correctional facilities.[30]

1.5. Summary and gaps in the current literature

As described in the earlier section, a heavier burden of poor health is evident among adults with histories of homelessness or incarceration compared with non-homeless or non-incarcerated counterparts. Two main approaches show that health status associated with homelessness/incarceration can be explained by individual risk factors or cumulative exposure to these events. As illustrated in Figure 1.1, in the individual risk factor approach, excess health burden is a manifestation of a poorer underlying health status and risk behaviors, which are commonly found among people with these experiences. In the structural exposure approach, more emphasis is made on describing mechanisms whereby the cumulative experiences of homelessness and incarceration influence health via psychological, physiological, or health care access process.[34]

Each approach may be equally important in understanding potential causal relationships between homelessness/incarceration and health burdens, as both baseline characteristics and cumulative life challenges likely contribute to adverse health conditions. However, evidence for the second approach is scant in the current literature. A limited body of studies report mixed results when temporal aspects of incarceration or homelessness experiences are accounted for.[15,26,30] For example, protective effects on all-cause mortality among prisoners or jail inmates have been observed during incarceration,[30,31] which disappear immediately after release.[32] Also, chronic homelessness has been associated with high mortality rates and low HIV prevalence.[15] Prior risk profiles or static measures of incarceration/homelessness experiences, which are considered as determinants of poor health outcomes in most studies, may not be able to explain these timevarying associations. Another limitation is that most findings are based on cross-sectional snapshots and there is little evidence of a temporal relationship between exposure and health outcome. Except for mortality, health conditions have been rarely assessed as incident risk, and temporal descriptions of life challenges associated with homelessness and incarceration are quite limited. Longitudinal data may provide critical information to explain the association between health and homelessness/incarceration, as seen in a limited body of studies.[5] For example, using a convenience sample of recently released NYC jail inmates, Freudenberg and colleagues described the detrimental effects of incarceration on social integration. They found that a great majority had difficulty enrolling in some government services/benefits (e.g., housing programs, Medicaid) that were restricted to former inmates, and got involved with illegal activities again. Lastly, temporal dynamics between homelessness and incarceration are rarely examined in analyzing relationship between these experiences and health even though these two events are strongly correlated.[43] Instead, existing studies often emphasize temporal characteristics of one of

these experiences, while using the other as a static measure that describes past experiences or study settings.[7]

1.6. Overview of the dissertation

1.6.1. Overall goals

To address limitations in the existing literature, this dissertation aims to capture timing and sequencing of jail incarceration and homelessness and identify group-based trajectories (i.e., a statistical method for grouping individuals based on similar trajectories) among a retrospective cohort study of NYC adults who were incarcerated or sheltered in NYC from 2001-05. The first three-year administrative records of jail incarceration and homeless shelter use are used to create a measure of complex trajectories of these longitudinal events. Another aim of the dissertation is to examine the association between trajectories of jail incarceration/homelessness and health outcomes during the last two years to test whether longitudinal exposure to these events contributes to risk of mortality and morbidity. It first makes a population-level inference by comparing the study population with non-incarcerated and non-sheltered NYC residents. Then, focusing on NYC adults with both jail incarceration and homelessness, it attempts to draw causal inference from associations between the revolving door pattern and mortality/HIV continuum care outcomes (e.g., retention in HIV care and viral suppression from laboratory-based surveillance data).

1.6.2. Specific aims Specific

aims are:

Aim 1: To identify and characterize distinct groups of individual-level trajectories of jail incarceration and homelessness among NYC adults. Trajectories of homelessness and

incarceration are hypothesized to be defined as discrete groups of individuals who share timing and sequencing of these events rather than drawn from a continuous distribution that predicts future events such as life course development of body mass index and psychological attributes. This inference is plausible because being homeless or incarcerated is a major life disruption, and the laws and policies usually focus on unique groups of homeless (e.g., chronic and episodic homelessness) and incarcerated adults (e.g., misdemeanors, felons).

Hypothesis 1a: There are distinct groups of individuals that are characterized by withingroup similarities and between-group differences in trajectories of jail incarceration and homelessness.

- Demographic and behavioral characteristics associated with adverse health conditions are more commonly found among people with both jail incarceration and homelessness compared with those with only jail incarceration or only homelessness.

Hypothesis 1b: A particular trajectory of jail incarceration/homelessness is associated with sociodemographic and criminal characteristics, and also with prior health status.

A trajectory of consistent jail incarceration and homelessness will be positively associated with being a minority male and charged with minor crimes such as loitering and making unreasonable noise.

- A trajectory of frequent transitions between short-term jail incarceration and homelessness will be positively associated with prior mental illness and substance abuse.

Aim 2: To test whether particular trajectories of jail incarceration/homelessness are associated with excess risk of mortality. Frequent transitions between jail incarceration and

homelessness are hypothesized to be independently associated with mortality outcomes including excess risk of all-cause, drug-related, and HIV/AIDS deaths.

Hypothesis 2a: Among the NYC adult population, exposure to incarceration or homelessness is associated with risk of mortality.

- A trajectory of frequent transitions between short-term jail incarceration and homelessness is associated with the highest risk of mortality across all trajectories.

Hypothesis 2b: Among NYC adult population with both jail incarceration and homelessness, risk of all-cause, drug-related, and HIV/AIDS deaths is higher among individuals with frequent transitions of short-term jail incarceration and homelessness compared with those with trajectories of more persistent jail incarceration and homelessness after controlling for individual-level risk factors.

Aim 3: To test whether particular trajectories of jail incarceration/homelessness are associated with discontinuity of HIV care. Frequent transitions between jail incarceration and homelessness are hypothesized to be independently associated with lower likelihood of retention in HIV care (at least two test results that are three months or greater apart within one-year period) and lower prevalence of viral suppression (<400 copies/ml).

Hypothesis 3: Among NYC adults living with HIV/AIDS with recent experiences of both jail incarceration and homelessness, lower likelihood of retention in HIV care and viral suppression will be associated with frequent transitions of short-term jail incarceration and homelessness versus trajectories of more persistent jail incarceration and homelessness.

1.6.3. Organization of the dissertation

The subsequent part of the dissertation consists of four chapters. Chapter 2 introduces concepts and analytic approaches of group-based trajectory modeling method, and presents trajectories of jail incarceration and homelessness (aim 1). It also describes baseline demographic and criminal characteristics and prior mental illness/substance uses in each trajectory group. In Chapter 3, the trajectory grouping from Chapter 2 is used as an exposure variable and associated with all-cause, drug-related, and HIV mortality outcomes (aim 2). Risk of death is compared between the study population and non-incarcerated/non-sheltered NYC residents via standardized mortality ratios (SMRs). Along with the between-population comparison, the association between risk of death and a particular trajectory among the study population will be examined via marginal structural modeling. Chapter 4 focuses on incarcerated/sheltered adults living with HIV/AIDS in NYC and examines whether trajectory groups of jail incarceration and homelessness is associated with discontinuity of HIV care (aim 3). Chapter 5 summarizes findings from Chapters 2-4 and discusses strength and limitations of the study. The dissertation concludes with policy implications and future research directions.

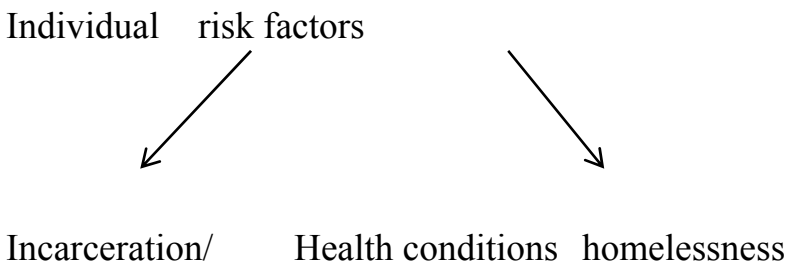
1.6.4. Significance of the dissertation

Trajectories of jail incarceration/homelessness measured in the dissertation expand current knowledge on the 'revolving door' problem. To our knowledge, no other study has undertaken a characterization of such trajectories to date. As temporal information such as timing and order of events is usually accurately captured in routine administrative data sources, and as the science of matching large datasets improves, measures of this type will allow for more opportunities to explicate connections between theories and operationalization, which strengthens internal validity and leads to more effective and practical solutions.[44] In addition, using the matched jail and shelter records over time, this dissertation yields more complete profiles of demographic,

behavioral, and criminal characteristics for adults cycling through jails and homeless shelters, compared with previous cross-sectional studies. Lastly, adopting rigorous methods to strengthen causal inference from registry data, it improves the limited body of empirical evidence on the extent to which individual risk factors and structural exposure contribute to adverse health conditions. Findings will benefit public health practitioners to design and implement more effective public health interventions, as limited resources can be more efficiently directed to population groups or time periods of particularly high health risk (e.g., two weeks after release among former substance users).

1.7. Data sources and study population

The main data source that gives rise to the study cohort of adults incarcerated/sheltered in NYC between 2001 and 2003 is an existing matched dataset, constructed using data from the NYC Department of Health and Mental Hygiene (DOHMH), NYC Department of Correction (DOC), and NYC Department of Homeless Services (DHS). This probabilistic matching process has been evaluated and validation results have been published.[1] The DOC registry of NYC jail admission records serves as the primary data source that generates the study subjects aged 16 years or older who have been incarcerated in NYC jails (Rikers Island and borough houses of detention in Brooklyn, Manhattan, and Bronx) during 2001 through 2005. These individuals have been probabilistically matched with the DHS single adult shelter registry and multiple DOHMH registries (vital statistics, HIV) that record NYC shelter use events, death events, and all HIV diagnosed prevalent cases between 2001 and 2005. The final matched data include demographic and criminal charge information, NYC jail admission/discharge information, NYC single homeless shelter use, death, HIV diagnoses, and HIV laboratory test results for NYC adults who have been incarcerated during 2001-05. In this dissertation, a homeless shelter use event is



considered as a surrogate of homelessness given that 90% of NYC homeless adults are reported to use municipal homeless shelters.[45]

Among 298,281 ever-incarcerated or sheltered individuals in the matched data, the dissertation focuses on those who were incarcerated or sheltered from 2001-03 because the first three years were used to construct trajectories of jail incarceration/homelessness. Those who died during 2001-03 (N=1,231) were excluded because one of the main study outcomes was mortality during 2004-05. The data were further restricted to those aged to 18 years or older in 2001 because the youngest age of NYC single adult shelter entry is 18 years old (N=194,536). Of these, individuals with both jail incarceration and homelessness (N=15,620) served as the primary study cohort, while incarceration-only (N=144,566) and homelessness-only populations (N=34,350) were included as comparison groups (Figure 1.2). Even though the revolving door phenomenon of incarceration and homelessness did not occur in the last two populations, their data were included to enhance the understanding of characteristics and trajectories of incarceration/homelessness in the study cohort. In addition, by comparing the primary study cohort with incarceration-only or homelessness-only populations, a dose-response relationship can be examined. The first three years of jail incarceration and homelessness data were used to construct trajectories of these events. As suggested in the previous study of NYC homeless population, three years would be a sufficient time to identify stable patterns.[46] The remaining two years in the study period were used to assess the risk of mortality and morbidity by trajectory group. Then mortality rates among the study cohort and incarceration-only and homelessnessonly populations were compared with those among non-incarcerated/non-sheltered NYC adults. Because individual-level data were not available for NYC adults with no history of incarceration/homelessness,

aggregate counts of mortality (numerator) and NYC population counts (denominator) were obtained from the NYC Office of Vital Statistics and the US Census 2000, respectively, to estimate risk of mortality in this unexposed group.

Chapter 2. Group-based trajectories of jail incarceration and homelessness among New York City adults who were incarcerated or sheltered in 2001-03

2.1. Introduction

Experiencing both jail incarceration and homelessness has been associated with excess mortality and morbidity risk in the US. Recent evidence points to unique health risk attributed to cumulative exposure to these experiences beyond individual-level risk factors. Understanding this structural exposure perspective is important because the identification of differential health risks by specific time points or temporal patterns provide important insight into potential mechanism through which body systems are affected by the experiences of being homeless or incarcerated.[1-3] In addition, the improved knowledge will make public health interventions more

effective because public health resources can be more efficiently directed to particular population groups or time periods associated with excess health risk.

Despite these potential benefits from employing the structural exposure perspective, little has been researched on transitions from/to jail incarceration and homelessness over time and their influence on morbidity and mortality, reflecting challenges of quantifying complexity and heterogeneity of exposure trajectories. A usual statistical treatment of repeated outcome data may not be appropriate because its main focus is how to make correct estimates from correlated data, rather than measure heterogeneity of trajectories of events.[4] Recently progress has been made in the methodology, known as group-based trajectory modeling, for capturing concepts of sequence, duration, and timing to explain social phenomena such as employment and criminal behaviors.[5] The purpose of this study was to identify and characterize distinct groups of trajectories of jail incarceration and homelessness among NYC adults via group-based trajectory modeling. Specifically, adults who experienced both incarceration and homelessness relative to those with only a single exposure were profiled in terms of baseline characteristics and trajectories of incarceration/homelessness. Then, whether a particular trajectory was associated with socio-demographic and criminal charge information, and also with prior health status was tested.

2.2. Methods

2.2.1. Samples

The primary study cohort consisted of 15,620 adults who were incarcerated and sheltered in NYC in 2001-03. As described in Chapter 1, data sources were combined administrative data from

NYC DOC jail admission and NYC DHS single adult shelter registries. The comparison groups included 34,350 adults with only homelessness, and 144,566 adults with only jail incarceration.

2.2.2. Study variables

The outcome variable was trajectory groups of jail incarceration/homelessness. This variable was obtained via group-based trajectory modeling based on admission and discharge information from both NYC jail and DHS single shelter registries during 2001 through 2003. First, these temporal records were first divided into time periods of 30 days ("windows"). Since the data covered a three-year period, each individual had 36 windows. Then, one of three events (incarceration, homelessness, community-dwelling) was identified in each window, which yielded a sequence of three possible status descriptors assigned to each individual. For example, if incarceration event(s) occurred during the 30-day period, that month was marked as incarceration. The same logic applied to homelessness events. Lastly, if no incarceration or shelter stays occurred, that month was marked as community-dwelling. Three-quarters (76%) of discharge locations at the end of all incarceration events during 2001-03 were recorded as community as opposed to other places such as state prisons (16%), state psychiatric hospitals (0.5%), and deportations (0.6%).

Independent variables included demographic and behavioral characteristics and types of criminal charges from DOC admission records for the incarcerated population. Specifically, demographic characteristics included age on June 30, 2002 (grouped as 18-24, 25-34, 35-44, 45-54, and 55-89 years), sex, race/ethnicity (grouped as Non-Hispanic white, non-Hispanic black, Hispanic, nonHispanic Asian, and other), and nativity (grouped as US-born and foreign-born). For neighborhood characteristics self-reported zip codes were matched to one of 42 NYC

neighborhoods using the United Hospital Fund's designation, an aggregate of adjoining zip codes, and categorized into low (< 10%), medium (10 to 20%), high (20 to 30%), and very high poverty neighborhoods (30% or higher) based on the percent of residents living below 200% of the federal poverty level, according to the US Census 2000.[6] Types of criminal charges, which may be indicative of particular behavioral characteristics, were classified as follows: violent (e.g., assault, murder, harassment, resisting arrest, and hazing), drug sales, drug possession, public administration (e.g., bail jumping, criminal contempt), property (e.g., arson, burglary), weapons (e.g., use, sale, and possession of weapons), quality of life (e.g., loitering, disorderly conduct, public lewdness), and sex crimes (e.g., rape, sexual abuse). For those with only homelessness, the same set of independent variables (except for residence, nativity, and criminal charge information) was obtained from DHS admission records. Lastly, because no data were collected to measure behavioral or mental health characteristics, proxy data were used to explore factors such as the influence of substance use. Specifically, trajectory outcomes were compared between individuals charged with drug possession or released to substance use treatment clinics and those who were not. Also, the association of being discharged to state psychiatric hospitals or mental health treatment clinics from jail or shelters with trajectory outcomes was evaluated to explore the potential role of prior mental illness.

2.2.3. Statistical analysis

For the study cohort (N=15,620), all possible pairs of individuals were created, and the degree of dissimilarity in sequences of three events between pairs was assessed by using three edit functions (inserting, deleting, and substituting). Each edit function had a weight assigned, which was determined by transition probabilities, and repeating this process over all possible pairs generated a distance matrix known as Levenshtein matrix.[7] Then, a hierarchical cluster analysis

with Ward method was performed, which resulted in non-overlapping clusters, representing trajectory groups of jail incarceration and homelessness. R 2.15 version (Vienna, Austria) was used to perform sequence (*TraMineR* package) and cluster analyses (*cluster* package). These processes required for sequence analysis are illustrated in Figure 2.1. For the comparison groups (144,566 adults with incarceration events only and 34,350 adults with homelessness only), a parametric version of sequence analysis, growth mixture modeling, was performed to identify group-based trajectories of incarceration or homelessness during 2001-03 using *poLCA* package in R 2.15 version (Vienna, Austria). Both methods are conceptually similar, but growth mixture modeling is more efficient than sequence analysis when large samples are analyzed (Figure 2.1).[8] For sequence analysis, the optimal number of trajectory groups was determined according to the ratio of mean within-distances to mean between-distances <0.5 and relative improvement of this ratio due to adding one more group to the cluster analysis solution.[9] This approach is appropriate for sequence analysis because it takes into account pairwise sequence differences used in clustering, unlike other cluster validation measures requiring for identifying variable-based differences ("dimension"; e.g., differences in age or sex between study subjects).[9] For growth mixture modeling, a two-step validation approach was used. First, from sequence analysis using 10% random samples of adults with only incarceration and 40% of random samples of those with only homelessness, which was the maximum sample size for *TraMineR* package, an optimal group solution was obtained according to the above criteria. It was more appropriate to determine valid cluster numbers from sequence data compared with methods based on specific dimensions. Second, growth mixture modeling was performed for the entire sample, and trajectory groups that were consistent with the optimal solution from the first step in terms of the number of groups and shapes of trajectories were considered final.

Descriptive statistics were computed to summarize individual risk factors of the study population and trajectory groups of jail incarceration and/or homelessness. Then, trajectory groups were associated with each of these baseline characteristics by means of bivariate analysis. Statistical significance of bivariate association (two sided p-value <0.05) was evaluated using chi-square test for categorical variables or independent t-test with bonferroni adjustment for continuous variables. Additionally, multivariate association between baseline characteristics and trajectory groups was evaluated via multinomial logit model. Yet, because of the large sample size, which increases the chance to detect small differences to be statistically significant, magnitude of differences rather than statistical significance was more emphasized to describe risk profiles of each trajectory group.

2.3. Results

The majority of 194,536 individuals who were incarcerated in NYC jail or spent at least one night at NYC single adult shelter during 2001-03 were male (86%), aged 18-44 years (70%), and non-Hispanic black or Hispanic (85%) (Table 2.1). Of this population, 8% (N=15,620) had both jail incarceration and homelessness experiences, while the remaining individuals experienced only incarceration (N=144,566; 74%) or only homelessness (N=34,350; 18%). The population with both exposures, compared with NYC residents, was disproportionately composed of nonHispanic black males (55% vs. 10%), non-Hispanic blacks aged of 35-44 years (27% vs. 5%), and residents of poor neighborhoods (40% vs. 24%). Compared with those with only one exposure, this population had an even higher proportion of non-Hispanic blacks (62% vs. 51% of the incarceration-only population or 52% of the homelessness-only population) and individuals aged of 35-44 years (41% vs. 31% of the incarceration-only population or 32% of the homelessness-only population). Another distinct characteristic among those with both incarceration and homelessness was a higher prevalence of substance use behaviors and serious

mental illness according to proxy measures. Lastly, having both incarceration and homelessness experiences, as opposed to only incarceration, was associated with particular criminal charges, including property crimes (41% vs. 26%) and drug possession (37% vs. 30%).

2.3.1. Adults with both incarceration and homelessness

Sequence analysis identified six non-overlapping groups of jail incarceration and homelessness trajectories among adults with both incarceration and homelessness (Figure 2.2; Table 2.2). Each plot in Figure 2.2 consists of stacked lines (y-axis) that represent individuals' sequences of monthly events over three years (x-axis). The majority (**Temporary**; N=9,467) spent most time outside of jail and shelters and sporadically experienced brief jail incarceration and shelter stays over three years. For example, individuals in this group were incarcerated for two or three days, and spent several months in the community before returning to jail or staying in shelters briefly. With these sporadic incarceration/homelessness events, they spent most time outside of shelter and jail. In contrast, another group that spent extensive amounts of time in shelters (median 662 days) without much interruption and had few brief incarcerations were classified as **Continuously homeless** pattern (N=691). Two trajectory patterns represented adults who increasingly used homeless shelters during later months after sporadic incarceration events (**Increasingly homeless**; N=1,793) and those who had early homelessness, followed by community stays with sporadic incarceration (**Decreasingly homeless**; N=1,033). Despite different sequencing, these two groups were similar in terms of aggregate time and frequencies of incarceration. Similarly, there were adults with early homelessness, followed by incarceration during later months (**Increasingly incarcerated**; N=1,343) and those with incarceration during early months and community-dwelling or sporadic homelessness afterwards (**Decreasingly incarcerated**; N=1,293).

Baseline demographic characteristics and neighborhood poverty were similar across all trajectory groups except for **Continuously homeless** individuals who were much older than the others (Table 2.3). Approximately 50% of individuals with **Continuously homeless, Increasingly incarcerated,** and **Decreasingly incarcerated patterns** had an indication of substance use, while prevalence of serious mental illness in **Continuously homeless** group was the highest. NYC jail inmates charged with drug possession, drug sales, property, and violent crimes were more likely to be **Increasingly** or **Decreasingly incarcerated** during 2001-03 compared to those with other crimes. In the multivariate analysis, all baseline characteristics except for sex, neighborhood poverty, and quality of care crimes were statistically significantly associated with trajectory groups (data not shown).

2.3.2. Adults with incarceration only

Among adults with only incarceration events, growth mixture modeling identified four trajectory groups that represent **Temporary**, **Decreasingly**, **Increasingly**, and **Continuously incarcerated** patterns (Figure 2.3). Sequence analysis based on 10% random samples confirmed that this cluster solution met the validity criteria (Figure 2.3; Table 2.2). 70% of this population had a brief history of incarceration over three years (**Temporary**), whereas 9% had extensive incarceration experiences characterized by lengthy jail stay during 2001-03 (**Continuously incarcerated**). The remaining 21% exhibited a structured pattern of incarceration during the early months, followed by community-dwelling (**Decreasingly incarcerated**; N=15,174) or vice versa (**Increasingly incarcerated**; N=16,282). Demographic, neighborhood, and criminal characteristics were in general comparable across the four trajectory groups, except for individuals with the **Continuously incarcerated** pattern whose percent charged with drug

possession, drug sales, and property crimes was almost two-fold higher than that among those with **Temporary** pattern (Table 2.4).

2.3.3. Adults with homelessness only

Similar to incarceration-only population, the growth mixture modeling identified four shelter use patterns among adults with homelessness only, which were determined to be optimal according to cluster validation criteria (Figure 2.4; Table 2.2). A majority of the homelessness-only population (59%) exhibited a small number of shelter admission episodes with brief shelter stays in 2001-03 (**Temporary**). 14% had a pattern of increasing use of shelter (**Increasingly homeless**), while 15% had a pattern of an intensive shelter use at the earlier periods and then later had sporadic brief shelter stays (**Decreasingly homeless**). Lastly, there was a pattern representing continuously-sheltered individuals over three-year period (**Continuously homeless**; 11%). **Temporary** users were much younger than those with the other patterns, whereas the opposite was found among **Continuously homeless** people (Table 2.5). Distributions of sex and race/ethnicity were similar across the four homelessness patterns.

2.4. Discussion

NYC adults with both homelessness and incarceration experiences during 2001-03 were predominantly minority males aged 25 to 44 years from poor NYC neighborhoods. While this population's characteristics were sociodemographically similar to that of the overall NYC incarcerated population during the same period,[10] there were particular characteristics that made this group unique, including high prevalence of substance use and property crimes compared to those with incarceration only? (Table 2.1). This finding was consistent with observations from a US national sample of jail inmates with homelessness collected in 2002.[11] Compared with adults

residing in NYC single adult homeless shelters during 2001-03 with no history of incarceration, adults with both experiences were disproportionately younger and male.

According to sequence analysis, there were non-overlapping clusters of individuals with distinct timing and sequencing of longitudinal experiences of incarceration and homelessness. By ignoring sequencing taking into account incarceration, homelessness, and community-dwelling periods, aggregate measures (e.g., total length of shelter stay, total number of incarceration events) would not identify these patterns. **Temporary** pattern was the largest group (61%), representing sporadic experiences of incarceration and homelessness with brief stays. Even if total number of incarceration or homelessness events was small in this pattern, it appeared to be most consistent with the concept of the revolving door pattern that composes of frequent occurrences of brief incarceration and homelessness, compared with the other patterns characterized by persistent jail or shelter stays. One possible mechanism that links **Temporary** pattern with the revolving door pattern is that brief exposure to incarceration and homelessness, as opposed to persistent stays in jail or shelters, is more likely to generate life disruption, which in turn lead to elevated stress levels and interrupt the continuity of essential health care. Another mechanism is that individuals with **Temporary** pattern are less likely to benefit from health care services in jails or shelters and receive proper discharge plans than those who stayed longer in these institutions.

All the other groups had either incarceration or homelessness sustained for a certain time period. In particular, two trajectory groups (**Increasingly homeless** and **Decreasingly homeless** patterns) had patterns of consistent homelessness and sporadic incarceration events, but were different from each other in terms of sequencing. One group had homelessness experiences

during the early months followed by few incarceration events, whereas the other had sporadic incarceration events transitioned to consistent homelessness during later months. These two contrasting patterns would not have been identified if incarceration/homelessness events were aggregated into total number of episodes or total length of stay. In addition, sequencing allowed for identification of consistent incarceration and sporadic homelessness trajectories (N=2,636; 17%), while the remaining 4% had homelessness persist throughout three-year observation time (N=691). A recent NYC study identified shelter use trajectories of more diverse timing and sequencing than the current study (e.g., initial shelter, early-mid shelter patterns).[10] This difference may be due to its smaller sample size (70 vs. 15,620) and shorter follow-up time (two years vs. three years).

Demographic and criminal characteristics were comparable across the six trajectory groups of incarceration/homelessness except for those with **Increasingly incarcerated** or **Continuously homeless** patterns, who were more likely to be charged with property and violent crimes (**Increasingly incarcerated**) or older (**Continuously homeless**) than the others. These baseline differences can be controlled for via statistical techniques such as inverse probability of treatment weighting, which then allows us to examine whether different trajectories of institutionalization influences health risk beyond individual-level risk factors. Once baseline characteristics are balanced out across trajectory groups, the exposure-outcome association may empirically point to unique contribution of temporal exposure to incarceration or homelessness to health risk or artifact of data affected by unobserved confounding.

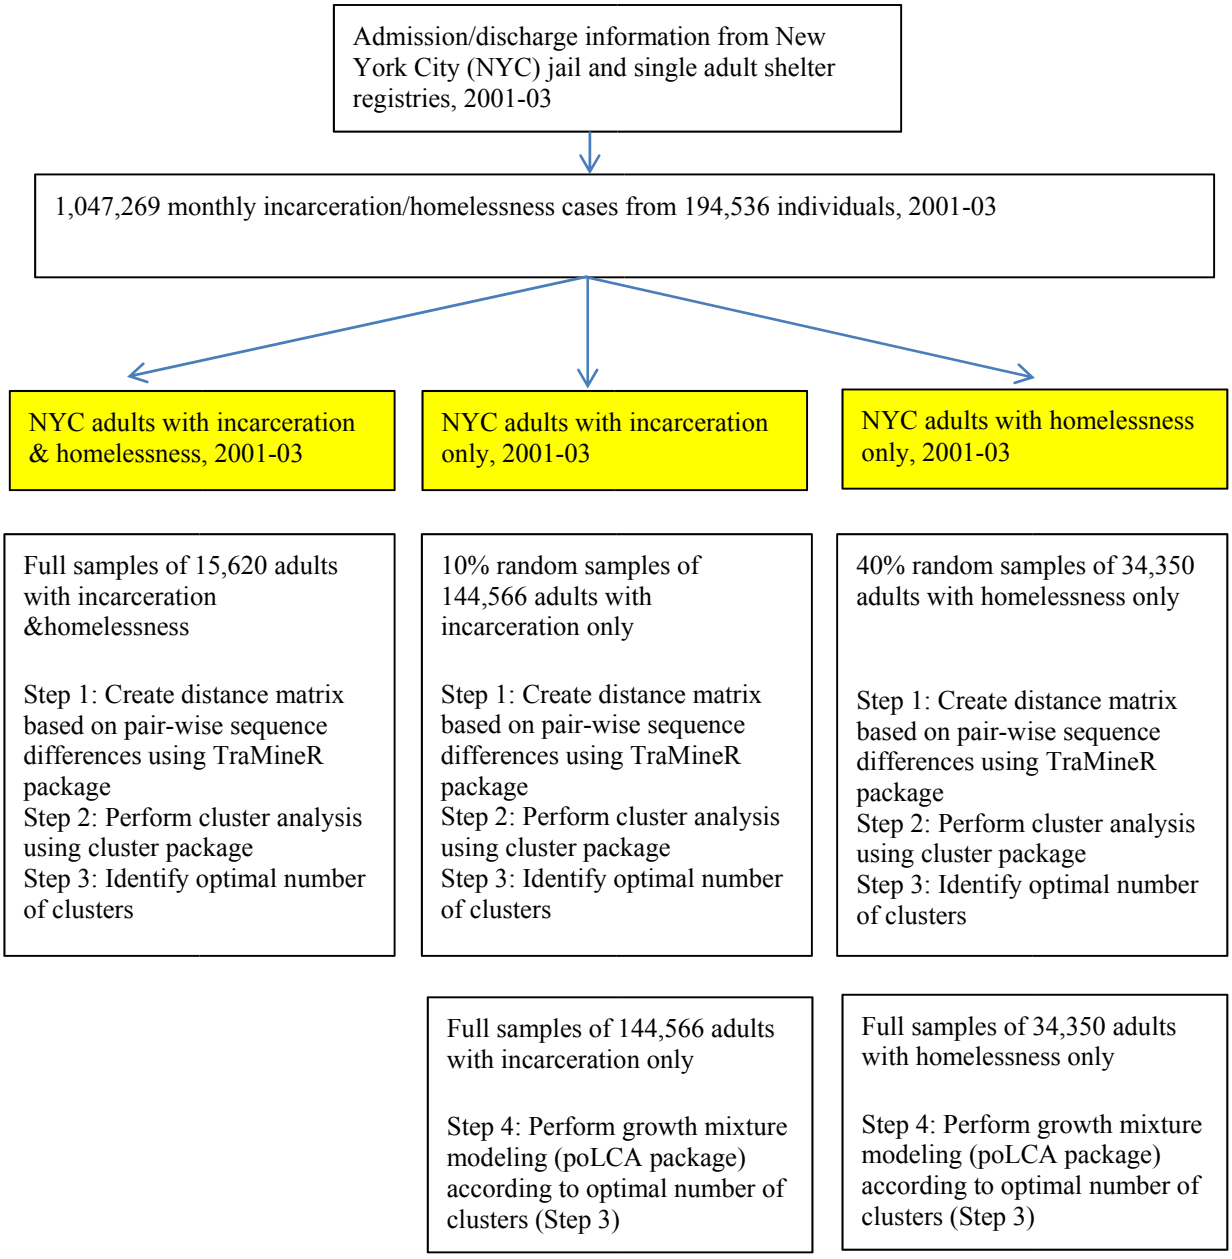
Within similar trajectory groups across the study cohort and comparison populations, short and frequent experiences of incarceration or homelessness appeared to be more common among

people with dual exposures relative to a single exposure. In addition, among the subset of incarcerated people with temporary trajectories, particular criminal characteristics such as property crimes and drug possession were more prevalent among those with both experiences as opposed to incarceration only. Given drug possession may be a proxy measure of substance use, these findings support the hypothesis that risk factors associated with adverse health conditions are more commonly found among people exposed to both incarceration and homelessness. High prevalence of property crimes may indicate material deprivation or financial stresses in this population,[11] but it may also reflect disruptive behaviors resulting from substance use or mental illness.

The study had several limitations. First, validity of trajectory grouping has been criticized because it is often difficult to replicate using a different population.[12] To address this limitation, I adopted a method to thoroughly ensure validity of the trajectory grouping. Specifically, I examined within and between distance ratios of trajectory groups among both the study cohort and comparison groups, and selected the trajectory grouping solution with the ratios that first became <0.5 (i.e., an indicator of valid grouping) and substantially decreased relative to the previous solution.[9] Second, a process of identifying groups of trajectories requires a strong assumption that heterogeneity of individual-level trajectories is derived from latent groups, not an underlying continuous distribution such as life course development of IQ, psychological attributes, and employment.[13] Even if this assumption seems plausible (e.g., being homeless or incarcerated is a major life disruption; the policy convention recognizes unique groups of homeless adults such as chronic and episodic homelessness),[14] more research is required to reinforce theoretical and empirical support for group-based trajectory modeling approach. Third, 16% of discharge locations from all incarceration events were recorded as state or federal prisons

according to NYC jail registry. Because time after release from jails and shelters was defined as community-dwelling in this study, there might be potential bias due to misclassifying actual prison stay as community-dwelling. When one-year uninterrupted community-dwelling after prison release was considered as a proxy of true prison stay, this type of event was concentrated among individuals with persistent incarceration during early months, followed by communitydwelling; 26% in this group had proxy prison stay whereas 0% to 10% of those with other patterns had the proxy prison stay. Taken together, misclassification error did not seem substantial, although interpretation of results for those who transitioned to community-dwelling from persistent jail stays should be made with caution. In addition, given that most homeless people also left shelters and stayed in the community, time after a homeless shelter stay was considered comparable to time after jail, which further justifies defining time outside of jails and shelters as community-dwelling. Fourth, homelessness, incarceration, and residing in the community were determined according to NYC single adult shelter use and NYC jail admission/discharge dates, which may underestimate true incarceration/homelessness events (e.g., street homelessness, incarceration outside of NYC). This bias, however, may be counterbalanced by overestimation of true community-dwelling, and improved validity and reliability of measures from administrative data as opposed to self-reports. Lastly, matched data from multiple registries do not have much information about risk behaviors, prior mental illness, and traumatic childhood events. Given that these characteristics have been associated with frequent incarceration and homelessness,[10,11] these unmeasured factors should be accounted for to assess health risk attributed to the revolving door pattern.

A main strength of this study is that combined administrative data for three years has allowed us to generate comprehensive profiles of the transient population and detailed information about jail



incarceration and homeless shelter use over three years, which we can then use to examine the influences of these patterns on health. A related strength is that longitudinal exposure of jail incarceration and homelessness was measured by group-based trajectories. Sequences of jail incarceration and homelessness events were accounted for, and summarized into distinct groups of individuals. These groups seem more nuanced than previously used time-aggregated groupings to measure homeless trajectories consisting of transitional (e.g., short-term homelessness followed by no such events), episodic (e.g., frequent homelessness), and chronic patterns (e.g., long-term homelessness without much interruption).[14] For example, using the conventional approach, individuals with **Temporary** pattern might have been classified as either episodic or transitional group. As transitions and specific timings can characterize particular life challenges, group-based trajectories potentially improve construct validity compared with a simple indicator or time-aggregated measures of each event.[15,16]

In conclusion, adults who were both incarcerated and sheltered in NYC during the study time period were more likely to be charged with property crimes and use substances than incarceration-only or homelessness-only population. Within this high risk population, groupbased trajectory modeling revealed diverse trajectories of incarceration/homelessness. While about 60% sporadically experienced brief jail and shelter stays, the remaining 40% had mixed experiences of jail incarceration and homelessness in various lengths and frequencies. Between some trajectory groups (e.g., **Temporary** vs. **Increasingly homeless**), basic demographic and criminal characteristics were similar, indicating that particular trajectories of incarceration and homelessness might plausibly be associated with adverse health conditions, independent of individual risk factors. This study finding highlights benefits of sequence analysis to generate temporal measures that more accurately capture complex trajectories. Whether or not

this more nuanced approach helps elucidate health risks remains an empirical question to be tested. When associated with health outcomes, trajectory grouping will contribute to understanding

mechanisms that exposure to incarceration and homelessness leads to health risk.

Figure 2.1. Diagrams of group-based trajectory modeling used for adults who were incarcerated in New York City jail or spent at least one night at New York City single adult shelter in 20012003

Notes: If both jail incarceration and homelessness occurred within a month, the number of jail and shelter days was counted and the event with higher numbers of days was assigned to that month. If an equal number of days were spent in both (678 out of 1,047,269 monthly incarceration/homelessness cases), the event less prevalent in individual-level sequence was assigned. Of 678 cases, 62% had jail incarceration assigned, and the remaining 38% were determined to be a homelessness event.

Chapter 3. Risk of all-cause, drug-related, and HIV mortality by three-year trajectories of jail incarceration and homelessness among incarcerated/sheltered New York City in 200405

3.1. Introduction

Frequent transitions between incarceration and homelessness ("the revolving door pattern") have been linked with adverse health conditions.[1,2] These experiences have been postulated as a process or determinant that damages biological systems and disrupts stable access to healthpromoting resources.[3-5] A limited body of studies provides evidence that mortality and morbidity risk is independently associated with temporal aspects of incarceration or homelessness experiences. For example, the time immediately after release as opposed to a later time among NYC former jail inmates was associated with greater risk of drug-related death,[6] while spending shorter time in shelters was associated with lower risk of new HIV diagnoses among NYC adults with homelessness.[7]

Prior risk profiles or static measures of incarceration/homelessness experiences may not be able to explain these time-varying associations. The previous chapter revealed diverse trajectory groups that represent complex three-year trajectories of jail incarceration and homelessness among NYC adults. For example, about 60% of NYC adults who were sheltered and incarcerated in 2001-03 experienced potentially more disruptive short-term incarceration and homelessness, while the remaining 40% exhibited trajectories of more persistent incarceration or homelessness. The purpose of this study was to test whether longitudinal exposure to incarceration/homelessness events, which were captured in trajectory groups from Chapter 2, contributed to risk of all-cause, drug-related, and HIV mortalities among NYC adults. The study first made a population-level inference by comparing mortality rates among incarcerated/sheltered NYC adults with those among unexposed NYC counterparts. Then,

focusing on those with both jail incarceration and homelessness, it attempted to draw causal inference from associations between the revolving door pattern and mortality.

3.2. Methods

3.2.1. Samples

The study population comprised of 15,620 individuals with both jail incarceration and homelessness, 144,566 individuals with incarceration-only, and 34,350 individuals with homelessness-only during 2001-03 as described in Chapter 1. A comparison group was nonincarcerated and non-sheltered NYC adults (N=5,830,224). For the study population, the combined administrative data from NYC jail and NYC single adult shelter registries provided jail incarceration/shelter use records and baseline demographic and criminal information. From the matched NYC vital statistics data, death events during 2004-05 were enumerated for this population. Because there were no individual-level data for the comparison group, two population-level data sources − US Census 2000 and NYC vital statistics registries − were used to estimate mortality during 2004-05.

3.2.2. Study variables

Primary outcome variables included all-cause deaths, deaths due to drug-related causes (F11-F16, F18-F19, X40-X42, X44), and deaths due to HIV (B20-B24) according to the International Classification of Disease, 10th revision.[8] The main exposure variable was the polytomous set of six trajectories of jail incarceration/homelessness from Chapter 2. Potential confounders for exposure-outcome association were identified using Directed Acyclic Graph (DAG), which is a conceptual tool to graphically describe a structural framework that variables are connected by directed arrows representing causal effects.[9] As illustrated in Figure 3.1, baseline demographic

(age, sex, race/ethnicity, neighborhood poverty) and behavioral characteristics (proxy substance use), type of criminal charges, and proxy prior mental health conditions were identified a priori as confounders of the jail incarceration/homelessness trajectory–mortality association. Study participation (i.e., censoring) was identified as a collider of that association (i.e., a common effect of exposure and outcome) because one would need to be found in NYC DOC/DHS registries to have a particular trajectory of incarceration/homelessness assigned, and would need to have survived in 2001-03. Because this study was conditioned on those who were homeless or jailed and survived during the study time period, additional analytic steps (described in the next section below) were taken to attempt to address any selection biases this introduced.

To account for differential time at risk, person-years were calculated and used as a denominator of mortality rates. For those who died in 2004-05, person-years were calculated as the time between January 1, 2004 and the date of death. Two years was used for those who were alive as of December 31, 2005. For non-incarcerated and non-sheltered individuals (comparison group), person-years were estimated by subtracting total person-years of the study population from proxy person-years of NYC adults in 2004-05 (=2*NYC adult population counts from US Census 2000).

3.2.3. Statistical analysis

Standardized Mortality Ratio

The mortality rate for each trajectory was compared with that among non-incarcerated/nonsheltered NYC adults by means of Standardized Mortality Ratio (SMR). Specifically, for adults with incarceration events only (N=144,566) or both incarceration and homelessness (N=15,620), the observed numbers of deaths was counted in each trajectory of jail

incarceration/homelessness, and expected numbers of deaths was obtained by multiplying the age-, sex-, race/ethnicity-, and neighborhood poverty-specific mortality rates of non-incarcerated/non-sheltered NYC residents by the person-years for each trajectory in corresponding age, sex, race/ethnicity, and neighborhood poverty strata. SMR was the ratio of the observed over the expected number of deaths. The Poisson method was used to compute 95% two-sided confidence intervals for the SMRs. For adults with homelessness only (N=34,350), an SMR was obtained using the same method, but not adjusted for neighborhood poverty because of the large amount of missing data
(homelessness often results in missing zipcode of residence).

Marginal structural modeling for NYC adults with both jail incarceration and homelessness To determine whether particular trajectories are causally associated with mortality, data should meet three causal assumptions. Under the exchangeability assumption, the probability of having each trajectory ("propensity score") should be independent of covariates that are causally related with mortality, which creates a condition that the risk of a health outcome would change as a result of the change in one's trajectory of incarceration and homeless shelter experiences.[10] To establish this condition, I first performed multinomial regression analysis using group-based trajectories of incarceration/homelessness (dependent variable), and baseline covariates that were identified as confounders via DAG (independent variables: age; sex; race/ethnicity; nativity; neighborhood poverty; a proxy measure of substance use; a proxy measure of mental illness; and criminal charges due to drug sales, violent crimes, weapon possession, public administration, property crimes, quality of life crimes, and sex crimes). This model, known as propensity score model, yielded an individual's probability of being in each trajectory group. Weighting the exposure-outcome relationship by an inverse of this score (inverse probability of treatment weight; IPTW)

blocks pathways from potential confounders to exposure and establishes exchangeability (Appendix I).[10] To minimize influences from large weights, I stabilized IPTW by replacing 1 in the numerator with a marginal probability of the observed trajectory.[10] The second causal assumption is positivity, which assumes that all study subjects should have positive probabilities of exhibiting all possible trajectories. Extreme IPTW, which are far off from 1, are indicative of nonpositivity.[11] As seen in Appendix II, estimated IPTW was 1 on average with a small standard deviation (i.e., IPTW was tightly distributed around 1), justifying no adjustment to meet the criteria for assuming adequate positivity.[11] The third causal assumption is the stable unit treatment value assumption (SUTVA), which assumes that the outcome of any study subject should depend on the trajectory group originally assigned to him or her, and not be influenced by the trajectory of other study subjects.[12] SUTVA are likely to be violated if some study subjects are geographically clustered such as living in the same shelters.[13] This potential dependency may bias the association between a particular trajectory and mortality. To address potential data dependency and violation of SUTVA, I adjusted for poverty levels of neighborhood of residency using IPTW. Mixed modeling or Generalized Estimation Equation approach was not used in this study because intraclass correlation, a measure of data correlation by four neighborhood poverty groups, was very small.

A marginal structural Cox proportional hazard model was then used to estimate the causal relationship between trajectories of jail incarceration/homelessness and mortality. Using IPTW to create a pseudo-population for which causal assumptions hold (see Appendix I), this model yields the marginal probability of the counterfactual random variables of mortality predicted by trajectory groups.[10] Unlike a conventional regression model, its coefficient of exposure variable

represents causal effects on the entire target population. A sandwich estimator for variance and a corresponding p-value were calculated because it was robust against model misspecification. To reduce potential bias from tied events,[14,15] Efron's approximation method was used.[16]

Missing data and imputation

To reduce potential bias resulting from excluding missing data in the analysis (sex: 1%, race/ethnicity: 1%, nativity: 1% excluding the homelessness-only population; neighborhood poverty: 25% excluding the homelessness-only population), I performed multiple imputations using *IVEware* software that adopted the sequential regression method.[17] Missing nativity and neighborhood poverty data were not imputed for adults who only had shelter use records because nativity information was not collected and neighborhood information was more than 50% missing in NYC shelter registry. Because of limited number of covariates and relatively large amounts of missing data in the neighborhood poverty variable, I tested whether imputation was a reasonable approach for individuals with both jail incarceration and homelessness and those with incarceration-only. From individuals with complete data, 25% was randomly selected and neighborhood poverty information was deleted. I then performed imputation and assessed agreement between actual and imputed neighborhood poverty data for the 25% samples randomly selected *a priori*. The estimated Kappa statistic was greater than the threshold (0.76 > 0.75), justifying imputing missing data (Appendix III).[18] Multiple imputations generated five imputed datasets, and combined results of five estimates that accounted for within- and betweenimputation variability were reported according to Schafer's approach.[19]

Four sensitivity analyses

Because the study did not collect information about behavioral and clinical characteristics associated with mortality such as injecting drug use (IDU), binge drinking, and chronic diseases, causal estimates from marginal structural modeling were potentially biased due to unobserved confounding. To address this issue, the study assessed the extent to which causal estimates might be influenced by bias due to unobserved confounding by performing two sensitivity analyses. The first one used the external adjustment method, which is derived from the equation that the confounded relative risk (RR) = true RR $\frac{\quad}{\quad}$, where P_{C1} = a probability of a binary confounder, C, among exposed, P_{C0} = a probability of C among unexposed, and RR_{CD} = RR between C and an outcome, D.[20] Setting the true RR = 1 and applying estimates from external sources to this formula, bias due to unmeasured confounders can be estimated. In this study, data from Survey of Jail Inmates 2002, the cross-sectional survey of 6,982 sampled inmates representative of the US jail population, provided estimated prevalence of unmeasured confounders (e.g., IDU experiences, binge drinking) and estimated associations between unmeasured confounders and exposure.[21]

The second sensitivity analysis was based on VanderWeele and Arah's bias equation, which is derived under three assumptions: 1) the association between the outcome and unobserved confounders is consistent across all levels of exposure and observed covariates; 2) the unmeasured confounder (U) is binary; 3) the prevalence of U is constant across all levels of observed covariates.[22] These assumptions allowed for estimating bias due to unobserved confounding by the formula: , where γ = association between outcome and U,

a = exposure, and x = measured covariates; otherwise, quantifying unobserved confounding bias would be almost impossible because observation studies often include a large number of covariates that generate many levels.[22] Because U was unknown, varying γ and a ratio of prevalence of U among the exposed over that among the unexposed (δ) were used, and in each level of γ and δ unbiased estimate of causal effect was obtained (= confounded RR / the estimated bias due to unobserved confounding). Since the variance was not affected by bias, I calculated the unbiased estimate of lower bound of confidence intervals using the same method, and examined whether it became below 1 (i.e., not statistically significant) or above 1 (i.e., statistically significant).

Along with unobserved confounders, prior exposure to jail incarceration/homelessness may lead to a biased association between a particular trajectory of these events and mortality. If three-year data were very different from previous years and not representing true trajectories (e.g., brief incarceration during early months in 2001-03 was a continuation of long-term persistent incarceration prior to 2001), low or high mortality risk might have been an effect of prior exposure rather than observed trajectories in 2001-03. In addition, excluding individuals who died during 2001-03 in the cohort might introduce survivor bias. To address these potential bias issues, I performed additional sensitivity analyses by 1) repeating sequence analysis and marginal structural modeling for adults aged 25 years or younger because they were less likely to have prior incarceration/homelessness experiences than older ones, and 2) examining characteristics of those who were excluded due to deaths during 2001-03 and repeating marginal structural modeling using the study cohort data that included early death cases.

All the analyses were performed using SAS 9.2 software (Cary, NC). Statistical significance was established if two sided p-value <0.05.

3.3. Results

During 2004-05, age-adjusted all-cause mortality rate among NYC adults who were both incarcerated and sheltered in 2001-03 was 1,086 per 100,000 person-years (95% Confidence Interval (CI) = 911, 1,288). It was similar to that among homelessness-only population (1,133 per 100,000 person-years, 95% CI = 1,036, 1,238), and higher than incarceration-only population (390 per 100,000 person-years, 95% CI = 347, 437) and non-incarcerated/non-sheltered NYC adults (826 per 100,000 person-years, 95% CI = 816, 837). Adjusted for age, the top four causes of death among those with both incarceration and homelessness included cancer, heart disease, HIV, and drug-related causes (Table 3.1). These were also the leading causes of death among the incarceration-only population, although cause-specific mortality rates were much lower than those among individuals with dual exposures. Compared with these two populations, adults with homelessness only and non-incarcerated/non-sheltered NYC adults were less likely to die of drug-related causes.

3.3.1. Comparisons with non-incarcerated/non-sheltered NYC adults

Compared with non-incarcerated/non-sheltered NYC adults of the same age, sex, race/ethnicity, and neighborhood poverty, incarcerated/sheltered adults with a **Temporary** trajectory had a 1.35 times higher risk of all-cause death (95% CI = 1.14, 1.59), and 4.60 times higher risk of drugrelated death (95% CI = 3.17, 6.46). In addition, the SMR for HIV mortality was 1.54 among those with a **Temporary** trajectory of incarceration and homelessness (95% CI = 1.03, 2.21). All the other trajectory groups in this population with both incarceration and homelessness

were not statistically different from unexposed NYC residents in terms of all-cause and HIV mortality risk.

An elevated risk of drug-related death was found among all trajectory groups except for **Increasingly incarcerated** and **Continuously homeless** patterns (Table 3.2).

Higher all-cause mortality risk was observed in all four trajectory groups of the homelessnessonly population compared to unexposed NYC residents, whereas a lower risk was found among the trajectory groups of incarceration-only population (Table 3.2). Stratified by trajectory groups

these two populations experienced higher risk of drug-related deaths than unexposed NYC residents in 2004-05, whereas none of the groups had an increased risk of HIV mortality.

3.3.2. Comparisons among six incarceration/homelessness trajectory groups

After balancing out differences in baseline covariates across six trajectory groups in the population with both incarceration and homelessness, all-cause mortality risk among adults with a **Temporary** relative to **Continuously homeless** pattern was 1.91 times higher (95% CI = 1.00, 3.68) during the two year follow-up period (Table 3.3). This pattern was also associated with risk of drug-related death and HIV death. Compared with **Continuously homeless** pattern, other trajectories yielded the null relative risk except for the elevated risk of drug-related death in **Decreasingly incarcerated** and **Increasingly homeless** patterns.

3.3.3. Sensitivity analyses

Despite evidence from marginal structural modeling, excess risk of mortality associated with the **Temporary** pattern among the population with both incarceration and homelessness might be due to unobserved confounding such as IDU and binge drinking. The results from sensitivity

analyses in Table 4 show that adjusting for IDU might have moved the estimated relative risk away from the null by 2.75%, whereas bias in the opposite direction was expected if adjusting for binge drinking (bias = 1.95%). In addition, Figure 3.2 illustrates how the lower bound of 95% confidence interval of relative risk for all-cause mortality is affected by adjusting for unobserved confounding. If prevalence of risk behaviors among the unexposed were greater than that among the exposed (i.e., $\delta < 1$), which was consistent with that of observed risk factors in this study (**Temporary** pattern versus **Continuously homeless** pattern), an unbiased estimate of the lower bound of 95% confidence interval would have moved away from 1. Along with sensitivity analyses for unobserved confounders, the study cohort was restricted to adults aged 25 years or younger and all the analyses were repeated. Similar to the main analysis, a majority had **Temporary** pattern in 2001-03. This pattern, as opposed to **Continuously homeless** pattern, was also associated with higher mortality risk, although the estimated association was not statistically significant due to a very small number of deaths.

Lastly, 146 individuals who died during 2001-03 were compared with the study cohort in terms of baseline characteristics and trajectories of incarceration/homelessness. Those who died earlier were older than those retained (on average 46 versus 36 years old), but there were no other systematic differences in baseline demographic and criminal characteristics, and leading causes of death between two groups (e.g., drug-related death: 29% vs. 23%, HIV death: 19% vs. 18%). The sequence analysis of these early death cases identified one trajectory group similar to **Temporary** pattern (N=64 deaths), and the other group (N=20 deaths) characterized by persistent homelessness (Figure 3.3). The remaining two groups (N=62 deaths) did not have sufficient observation time to generate meaningful trajectories; they were characterized by the length of observation time rather than events. After those with valid trajectories (N=84 deaths)

were put back to the study cohort, the marginal structural modeling analysis were repeated. Excess all-cause and HIV mortality risk associated with **Temporary** pattern were consistently found. However, the association between trajectory groups and risk of drug-related death was attenuated and no longer statistically significant, although the magnitude of drug-related mortality risk was still the highest among **Temporary** pattern.

3.4. Discussion

In the retrospective cohort study of incarcerated/sheltered NYC adults, sporadic exposure to brief jail incarceration and homelessness (**Temporary** pattern) was associated with excess risk of allcause, drug-related, and HIV deaths during a two year follow-up period. This elevated mortality risk was consistently found when compared with non-incarcerated/non-sheltered NYC adults as well as those with **Continuously homeless** pattern. In particular, NYC adults with this **Temporary** pattern were five times more likely to die of drug-related causes than unexposed NYC residents of the same age, sex, race/ethnicity, and neighborhood poverty. Excess risk of drug-related deaths was also observed in the other trajectory groups except for **Increasingly incarcerated** and **Continuously homeless** patterns, whereas all-cause and HIV mortality risk was not associated with trajectory groups other than **Temporary** pattern.

Compared with non-incarcerated/non-sheltered NYC adults, all-cause mortality risk was greater among those with homelessness-only, and smaller among those with incarceration-only according to SMR analysis. These findings were consistent with existing evidence from previous studies that homelessness was an independent mortality risk factor in the United Kingdom[5] and time at prison or jail was related with lower risk of age-adjusted all-cause mortality among prisoners or jail inmates as opposed to the US general population.[23,24] In general, the SMR was greater among the incarceration and homelessness population with **Temporary** pattern, as

opposed to incarceration-only or homelessness-only populations. However, pairwise comparisons of SMR between different populations should be made with caution because SMR inference was specific to each population (i.e., the reference population served as counterfactual of the exposed population) and a limited number of confounders were accounted for. For example, a relatively high observed SMR among the homelessness-only population relative to the other populations may reflect residual confounding associated with their older ages or other unmeasured residual confounding that influences the observed homelessness-mortality association.

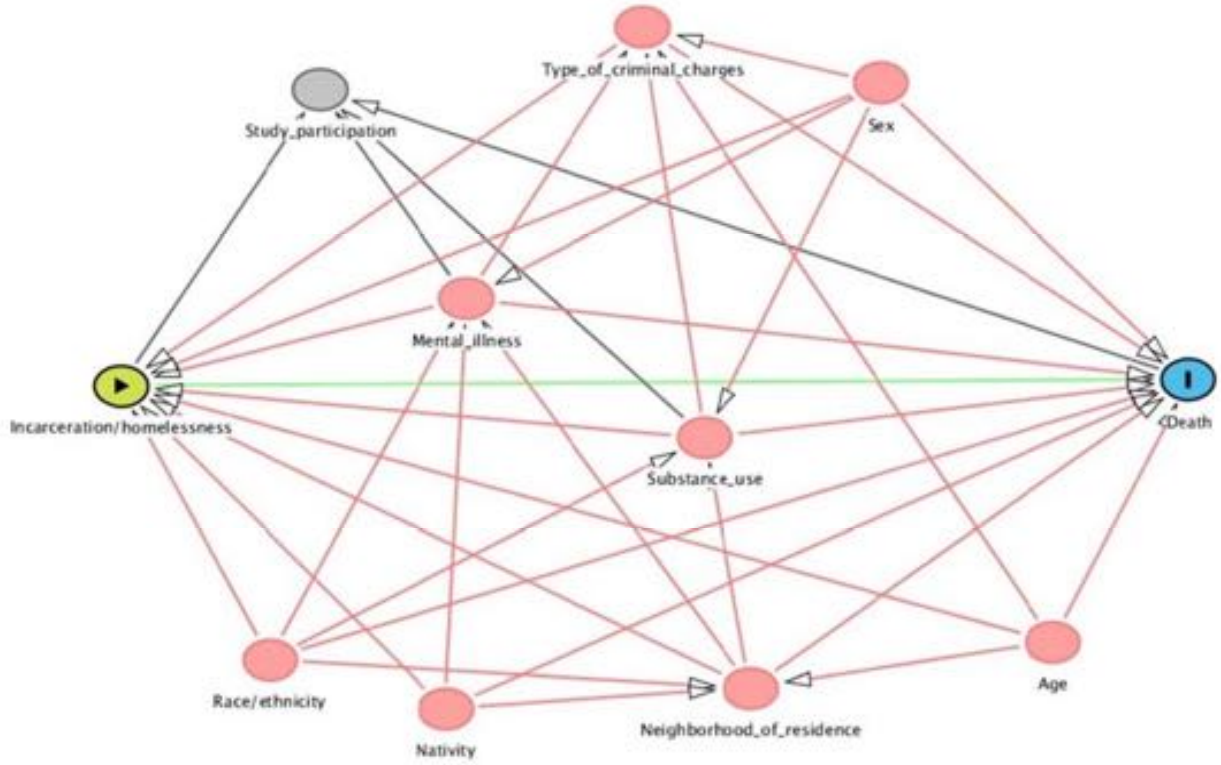
Excess risk of all-cause mortality among ever-incarcerated and ever-sheltered individuals with **Temporary** pattern, especially as opposed to those with **Continuously homeless** pattern, may point to health burdens attributed to the revolving door pattern. Two methods were employed to assess whether this observation was potentially the result of an artifact of confounding, including IPTW and sensitivity analyses. Both results ascertained causal assumptions and suggested that the observed association was unlikely to be an artifact of confounding, strengthening this inference. One possible mechanism is disruption of medical care due to transitions from brief jail incarceration or homelessness to community-dwelling, which may also explain the association between **Temporary** pattern and high HIV mortality risk because continuity of antiretroviral care is critical for survival among people living with HIV/AIDS.[25] In contrast, for those with trajectories of persistent homelessness or incarceration relative to the **Temporary** pattern, essential medical care is less frequently to be disrupted or exposed to hazardous environments in the community (e.g., drug intake) for at least two-year follow-up period. Another possible explanation for the **Temporary** pattern-mortality association is that frequent releases from jail

may increase a chance for drug overdose as abstinence during jail stay decreases drug tolerance.[26] This mechanism has been supported by evidence of excess risk of drug-related death in the previous US and United Kingdom studies.[2,27,28] Yet, another sensitivity analysis examined possible survivor bias by taking into account early death cases that were excluded, and revealed that excess risk of drug-related death associated with the **Temporary** pattern in the current study was less apparent. Extensive discussion on this finding can be found in the following limitations section. Lastly, some researchers attribute excess mortality risk associated with incarceration or homelessness as cumulative stresses,[3,5] but this explanation seems less convincing than the others given the similar sensitivity analysis finding among the cohort aged 25 years or younger, the short observation time, and lack of data about differential stress levels across trajectory groups.

All trajectory groups except for **Increasingly incarcerated** and **Continuously homelessness** patterns were associated with risk of drug-related death, compared with unexposed NYC residents. Incarceration during later time or consistent shelter stays throughout 2001-03 were more likely to remain incarcerated or sheltered during subsequent two years than other trajectories, which might decrease circumstances to use drugs. Unlike drug-related death, risk of HIV death was not elevated among NYC adults who had incarceration/homelessness sustained for certain time points. During uninterrupted stays, they might benefit from medical services or referrals offered in shelters or jail. Yet, more data about availability and delivery of services for NYC jail inmates or shelter users with HIV/AIDS are warranted to test this hypothesis.

This study has some limitations. First, only aggregate data were available for nonincarcerated/non-sheltered NYC adults. As mentioned earlier, inference from the SMR analysis should thus be made with caution because relative risk could be biased due to residual

confounding beyond age, sex, race/ethnicity, and neighborhood poverty. Second, similar to measurement error pertaining to the exposure variable in the Chapter 2, death outcomes were likely to be underestimated because deaths outside of NYC (e.g., about 6.5% of annual deaths among NYC residents according to National Center for Health Statistics) were not captured. This is likely to bias the estimated association toward the null under the assumption that measurement error is independent of trajectory groups. Third, even though bias due to unobserved confounding due to certain measures was examined via sensitivity analyses, there might be other sources of undetected confounding that moves the relative risk toward the null. Fourth, because individuals who died during 2001-03 in the cohort were excluded, the estimated RR might be affected by survivor bias. Even if causes of death and baseline characteristics were similar between those who died earlier and those retained, the sensitive analysis showed that the relationship between trajectory groups and drug-related mortality became attenuated and nonsignificant after adding early death cases. With survivor bias, the mortality rate among the unexposed is usually inflated because the exposed is required to survive to receive a treatment such as drugs or surgical procedures; as a result, biased RR is smaller than true one.[29] In this study, the opposite occurred. After early death cases were re-added to the cohort (i.e., potential survivor bias was accounted for), age-adjusted drug-related mortality among **Temporary** pattern (the exposed) increased two fold, whereas **Continuously homeless** individuals (the unexposed) experienced five-fold increase. This may reflect the younger ages of early drug-related deaths among the unexposed, or the study design that actual treatment was not provided to the exposed. Longer follow-up time is required to determine presence of survivor bias because 1) the sensitivity analysis result is based on a very small number of drug-related deaths (e.g., death count increased from one to three when early deaths were added to the **Continuously homeless** group); 2) trajectory grouping may



not be reliable among early deaths (e.g. 84 early deaths had two-year exposure time on average, and one extra year would be a sufficient time to have their
trajectory group membership changed). Lastly, two years may not be a sufficient time to assess mortality risk due to chronic diseases. Long-term health impacts of some trajectories other than the revolving door pattern may be different from those observed for two immediate years.

Despite these limitations, the study has some important strengths. First, by linking various trajectories of incarceration/homelessness and mortality outcomes, this study assessed mortality risk associated with complex transitions among jail incarceration, homelessness, and communitydwelling. In particular, this allowed us to empirically test the structural exposure perspective that the revolving door pattern contributes to adverse health conditions. Second, the study explicitly tested and adopted analytic methods to establish causal assumptions from analysis of administrative data. While causal inference from observational data is fraught with methodological challenges, these techniques improve the internal validity of measuring the unique health burdens associated with longitudinal exposure to jail incarceration/homelessness beyond individual-level risk factors.

In conclusion, longitudinal exposure to incarceration and homelessness in 2001-03 was independently associated with mortality risk during two year follow-up period among NYC adults. In particular, those with sporadic exposure to brief incarceration and homelessness experienced excess risk of all-cause, drug-related, and HIV deaths. It implies that life disruption due to brief exposure to these events exerts negative health impacts, providing important evidence for the structural exposure approach. This finding suggests targeting a group of

individuals based on patterns of incarceration/homelessness for public health interventions to prevent them from cycling through jails and homeless shelters and promote community linkage programs for continuity of care.

Figure 3.1. Directed Acyclic Graph for causal relationship between being exposed to both incarceration and homelessness and all-cause mortality

Notes: Green line = causal path, red line: biasing path, green circle = exposure, blue circle =

outcome, red circle = common cause of exposure and outcome, grey circle = common effect of exposure and outcome.

Table 3.1.Age-adjusted mortality rates per 100,000 person-years (95% Confidence Interval) in 2004-05 among 194,536 adults who were incarcerated in New York City jail or sheltered in New York City single adult homeless shelter during 2001-03

New York City	Total study	Incarceration & homelessness	Incarceration only	Homelessness adults† only	population
All-cause mortality rates per 100,000 in 2004-05	826 (816,837)	840 (785,897)	1,086 (911,1288)	390 (347,437)	1,133 (1036,1238)

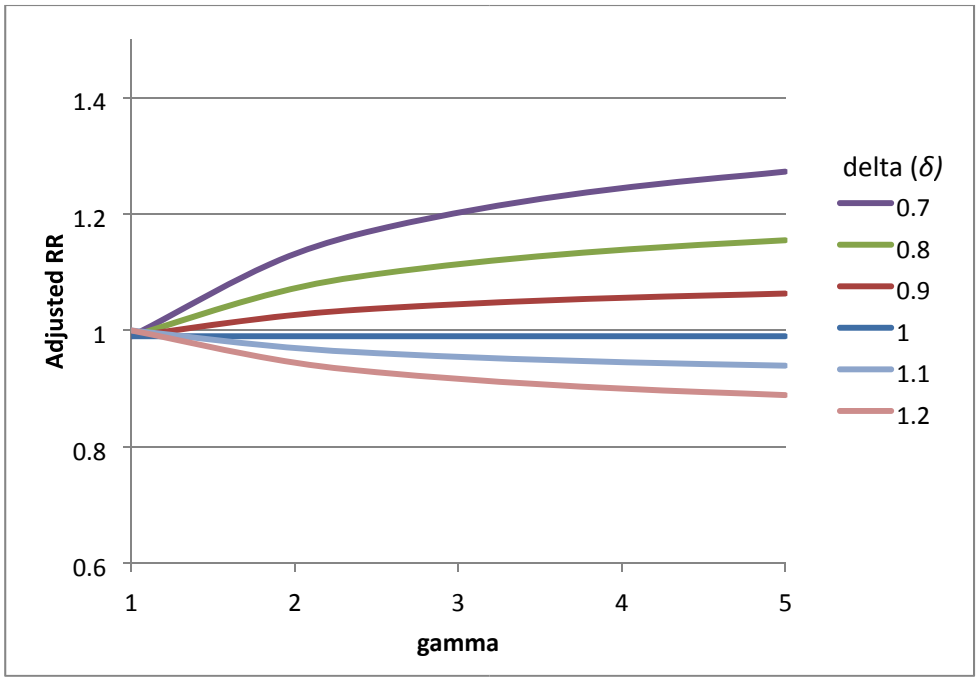
Abbreviations: CI, confidence interval; RR, relative risk.

Notes: Numbers in bold indicate statistical significance at $p < 0.05$.
Inverse probability of treatment weight was used to control for bias due to confounding. Potential confounders included age, sex, race/ethnicity, nativity, neighborhood poverty, a proxy measure of substance use, a proxy measure of mental illness, criminal charges due to drug sales, violent crimes, weapon possession, public administration, property crimes, quality of life crimes, and sex crimes.

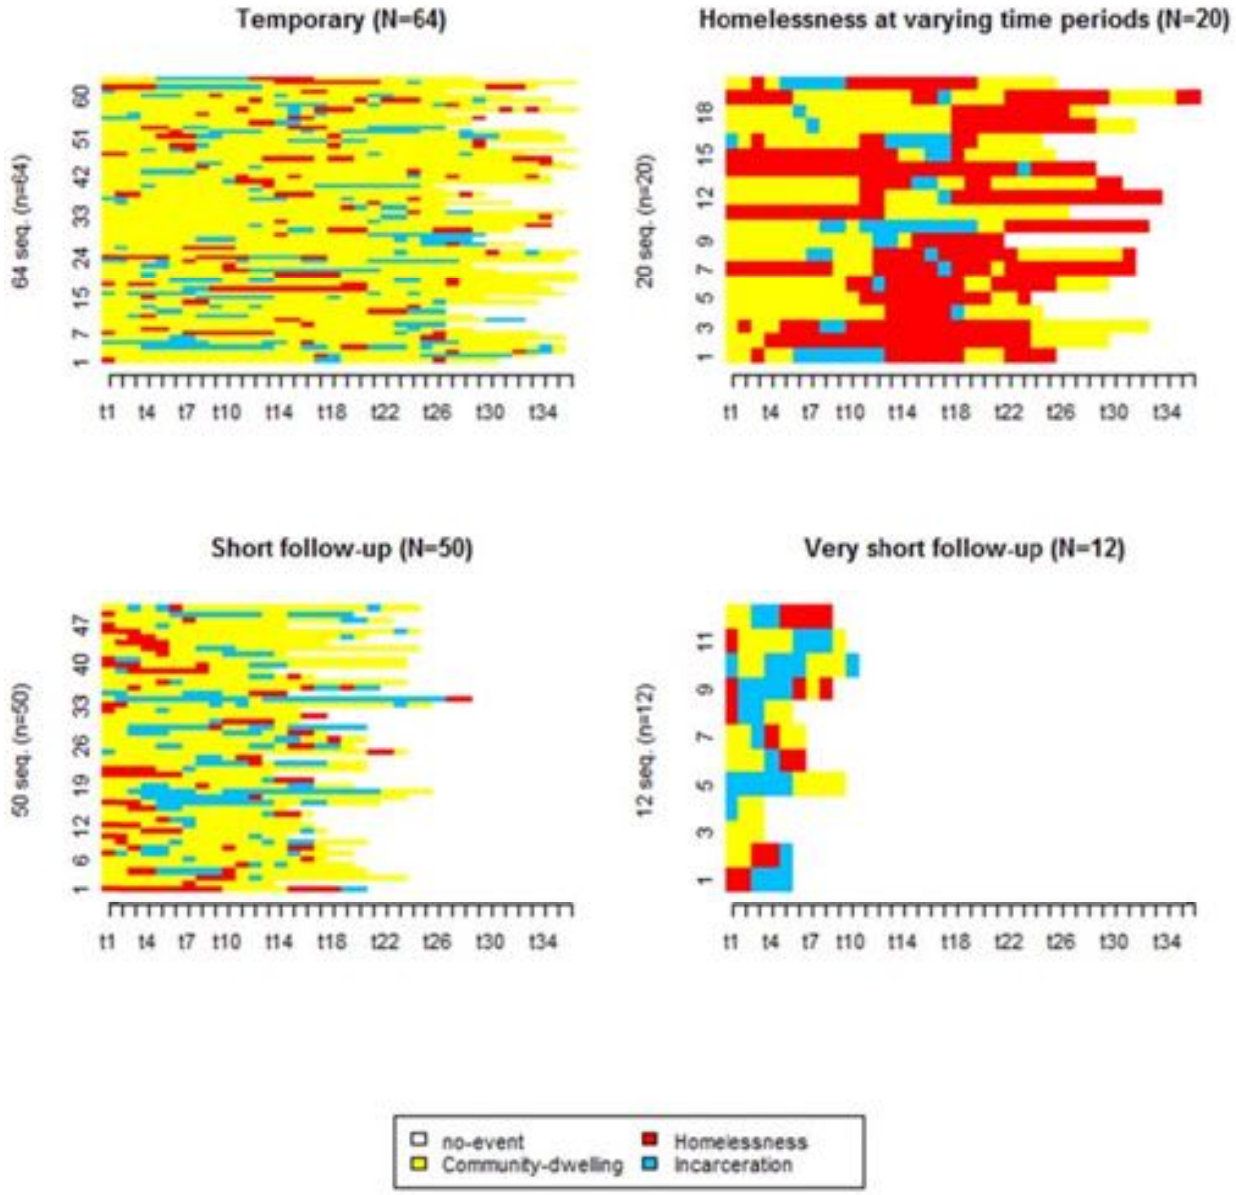
[b] Due to zero HIV cases in the Continuously homeless pattern, three trajectories of homelessness (Increasingly, Decreasingly, and Continuously homeless patterns) and two trajectories of incarceration (Increasingly, and Decreasingly incarcerated patterns) were collapsed into homelessness and incarceration groups, respectively.



[c] Wide confidence intervals reflect small number of outcome cases. As seen in Table 2, one drugrelated death occurred among individuals with the Continuously homeless pattern, which was used as a reference group.

Table 3.4. External adjustment for all-cause mortality and the revolving door pattern among 15,620 adults with jail incarceration and homelessness, New York City, 2004-05

	RR_{CD}	P_C	OR_{EC}	True RR_{ED}	P_E	Apparent RR_{ED}	% bias
Binge drinking	1.40	0.49	1.26	1.00	0.69	1.02	1.95
IDU	4.20	0.27	0.92	1.00	0.69	0.97	-2.79



Notes: Because there was no existing study that measures the revolving door pattern of jail incarceration and homelessness, I defined exposure as having both jail incarceration and homelessness experiences among participants of Survey of Jail inmates, 2002. To be consistent with the reference group in the current study (continuously homeless pattern), I defined nonexposure as having previous and current homelessness experiences among jail inmates. RR_{CD} = relative risk between confounder and outcome (source: evidence from the literature), P_C = prevalence of confounder in the study population that consists of jail inmates with homelessness experiences (source: Survey of Jail inmates, 2002), OR_{EC} = association between confounder and exposure (source: Survey of Jail inmates, 2002), P_E = prevalence of exposure in the study population (source: Survey of Jail inmates, 2002), Apparent RR_{ED} = confounded relative risk of all-cause mortality by the revolving door pattern.

Figure 3.2. Estimated lower bound of 95% confidence intervals of relative risk for all-cause mortality by the revolving door pattern adjusted for an unobserved confounder (*U*) among 15,620 adults with jail incarceration and homelessness, New York City, 2004-05

Abbreviations: CI, confidence interval.
Notes: the lower bound of 95% CI of relative risk of all-cause mortality by the revolving door pattern was 1.00 from Table 3. $P(U=1|a=1,x)$ was arbitrarily set as 0.5.
U = unmeasured confounder; $\delta = P(U=1|a=1, x) / P(U=1|a=0,x)$; $\gamma = RR$ of all-cause mortality by U.
Key parameters are comparable between this approach and external adjustment (Table 3) such that $U=P_C$, $\delta \approx OR_{EC}$, $\gamma = RR_{CD}$.

Figure 3.3. Four non-overlapping groups of jail incarceration/homelessness trajectories according to sequence analysis among 146 New York City adults with both jail incarceration and homelessness who died during 2001-03 and were excluded from the study cohort

Chapter 4. Three-year trajectories of jail incarceration and homelessness and their association with retention in HIV care and viral suppression among incarcerated/sheltered New York City adults living with HIV/AIDS

4.1. Introduction

Maintaining adequate HIV medical care is a critical component of survival for people living with HIV/AIDS (PLWHA).[1,2] Housing stability has been considered to be one of the important determinants of retention in essential HIV medical care and viral suppression because it helps PLWHA adhere to routines such as making regular visits to doctors and taking antiretroviral medications.[3] Housing stability may also provide intangible resources such as a stronger social network and sense of identity, which may motivate individuals to avoid risk behaviors and follow treatments to maintain health.[3] Empirical evidence to support this relationship has been documented among PLWHA with histories of homelessness. For example, according to selfreported longitudinal data from a representative sample of NYC PLWHA, receiving assistance for housing problems was positively associated with higher odds of appropriate HIV medical care.[4] Similarly, several studies have reported higher likelihood of adherence to antiretroviral treatment among stably-housed PLWHA versus their homeless counterparts.[5-7] However, despite high prevalence of HIV among the incarcerated population in the US, this association has rarely been tested among incarcerated PLWHA; current evidence is mainly concentrated on disrupted HIV care post release.[8-10] Because incarceration is strongly correlated with homelessness, and because experiences of both events affect housing stability, it is important to take into account dynamic aspects of incarceration events along with homelessness to improve validity of the housing stability-continuity of HIV care association. The purpose of this analysis was to examine whether retention and quality of HIV care was associated with different patterns of incarceration/homelessness among NYC PLWHA with recent experiences of both jail incarceration and homelessness, using a measure that captures timing and sequencing of

jail incarceration and homelessness from sequence analysis. Specifically, the study tested the hypothesis that frequent transitions between incarceration and homelessness, which suggests greater housing instability, are associated with lower likelihood of retention in HIV care.

4.2. Methods

4.2.1. Samples

The study population included 1,173 NYC adults who were diagnosed with HIV/AIDS and spent at least one night in both NYC jail and NYC single adult homeless shelters during 2001-03. The combined administrative data from NYC jail and NYC single adult shelter registries provided jail incarceration/shelter use records and baseline demographic and criminal information. From the matched NYC HIV surveillance registry, data about HIV/AIDS diagnoses, viral loads, and CD4 counts were obtained for this cohort. The comparison group comprised of nonincarcerated/non-sheltered NYC PLWHA who were diagnosed and alive prior to 2004 from the NYC HIV surveillance registry.

According to a New York State regulation, all viral load and CD4 test results should be reported as of June 1, 2005, an expansion of the previous law that required reporting of only detectable viral load results. This mandatory reporting law has been effective in almost completely capturing HIV laboratory test results in NYC.[11] Because undetectable viral load results (50 copies/ml or less) were missing in the NYC HIV surveillance data before this regulation, the study used the one-year period between June 2005 and June 2006, as opposed to 2004-05 years, to obtain HIV care outcomes.

4.2.2. Study variables

Two primary outcome variables were examined in this analysis: (1) retention in HIV medical care and (2) viral load suppression.[2] Retention in HIV medical care was established if there were at least two viral load or CD4 tests during June 2005-June 2006, which were ≥90 days apart.[1] Viral load suppression was defined as being achieved if there was at least one record with a viral load of <400 copies/ml during the 12-month period.[2] The viral load suppression outcome was calculated only for those with viral load test results (N= 698).

The exposure variable was defined using group-based trajectories of jail incarceration/homelessness. In NYC, PLWHA experiencing homelessness have a legal right to obtain permanent housing and rental assistance through the NYC HIV/AIDS Services Administration. Instead of using trajectory groups from Chapter 2, I re-ran sequence analysis to identify trajectories that might be unique to NYC PLWHA with recent jail incarceration and homelessness that represented 8% of the original cohort, which could have been collapsed within more general patterns in the study cohort. Detailed analytic steps of sequence analysis were described in the method section of Chapter 2. Potential confounders for exposure-outcome association were identified by constructing a DAG specific for this analysis.[12] These included baseline demographic (age, sex, race/ethnicity, neighborhood poverty) and behavioral characteristics (proxy substance use), type of criminal charges, proxy prior mental health conditions, age of HIV diagnoses, and stage of HIV infection (HIV or AIDS). Similar to the mortality analysis in Chapter 3, to be eligible for this analysis, one had to survive after 2001-03 to be included in the study cohort, and censoring death cases could potentially act as a collider.

However, this potential bias was unlikely because no actual death in the study cohort occurred during 2001-03 according to a review of the NYC HIV surveillance registry data. A small number of deaths were identified during the follow-up time and these were reflected in the person-years calculation. For deaths, the midpoint of the year of death (e.g., July 1, 2004) was assigned, or 0.5 person-years for deaths in 2004 (N=33), and 1.5 person-years for deaths in 2005 (N=41), while 2.5 person-years were assigned to those who survived during the follow-up period or died in 2006.

4.2.3. Statistical analysis

First, descriptive statistics of baseline characteristics and HIV care outcomes were summarized across trajectory groups of incarceration and homelessness. Bivariate association between each of these characteristics and trajectory groups were evaluated using chi-square test for categorical variables or independent t-test with bonferroni adjustment for continuous variables. Then, marginal structural log-linear Poisson regression analysis with an offset of person-years was performed to estimate adjusted relationships between trajectories of jail incarceration/homelessness and HIV care outcomes. As described in Chapter 3, a stabilized inverse probability of treatment weight (IPTW) was derived from a propensity score model using trajectory groups (dependent variable) and baseline demographic, behavioral, and criminal characteristics (independent variables). Estimates from marginal structural modeling were weighted using IPTW, ensuring that weighted data met the assumptions for exchangeability (balanced baseline characteristics across trajectory groups; Appendix IV), positivity (tightly distributed IPTW with one as a mean value; Appendix V), and stable unit treatment value

(adjusting for poverty levels of neighborhood residency to address potential data dependency among some study subjects).[13-15] A sandwich estimator for variance and a corresponding p-value were calculated because it was robust against model misspecification.[14]

Missing data and imputation

Multiple imputations via *IVEware* software[16] were performed to address missing data using the whole study population (sex, race/ethnicity: 1% missing, nativity: 1% missing excluding homelessness-only population; neighborhood poverty: 25% missing excluding homelessnessonly population), which generated five imputed datasets. A subset of PLWHA was then recreated and combined results of five estimates were reported according to Schafer's approach, which accounts for within- and between-imputation variability.[17]

Sensitivity analyses

Because the study did not collect information about behavioral and clinical characteristics associated with retention in HIV care or viral suppression (e.g., IDU), causal estimates from marginal structural modeling were potentially biased due to unobserved confounding. To address this issue, the study assessed the extent to which causal estimates might be influenced by bias due to unobserved confounding by performing the sensitivity analysis proposed by VanderWeele and Arah.[18] However, unlike Chapter 3, the external adjustment method could not be used because of lack of existing public data that represented the population with both HIV/AIDS and jail incarceration/homelessness in the US.[19]

Along with the sensitivity analysis for unobserved confounding, all the analyses were repeated using NYC PLWHA with homelessness-only and those with incarceration-only. Because NYC PLWHA staying at shelters during 2001-03 were likely to receive housing assistances and benefits through effective NYC DHS referral system to HIV/AIDS Services Administration (i.e., immediately referring self-identified PLWHA to emergency single room occupancy units),[20] a particular trajectory of homelessness might also represent differential housing instability; associations between trajectories and continuity of HIV care among those with both incarceration and homelessness would be replicated in this population. For NYC PLWHA incarcerated or recently released from NYC jails, various housing services were also available. Yet, transition from jail to the housing was reported to be less organized and effective than that from shelters during 2001-03,[21] which could generate a unique association between trajectories of incarceration and continuity of HIV care.

All the analyses except for sequence analysis (R 2.14.2) and imputation (*IVEware*) were performed using SAS 9.2 software (Cary, NC). Statistical significance was established if two sided p-value <0.05.

4.3. Results

The majority of 1,173 individuals living with HIV/AIDS who were incarcerated in NYC jail and spent at least one night at NYC single adult shelter during 2001-03 were male (84%), aged 18-44 years (82%), and non-Hispanic black or Hispanic (95%) (Table 4.1). This population, compared with non-incarcerated/non-sheltered NYC PLWHA, was disproportionately male (84% vs. 69%) and non-Hispanic black (65% vs. 45%). In contrast, the percent of non-Hispanic whites (4% vs.

21%) and residents living in the medium poverty neighborhood (14% vs. 29%) was much smaller in the study cohort relative to non-incarcerated/non-sheltered NYC PLWHA, while age distribution and stage of HIV infection were similar between two groups.

Figure 4.1 shows that jail incarceration and homelessness events over 2001-03 were best represented by five unique trajectories, and this cluster solution was determined to be optimal (Table 4.2). Among 1,173 PLWHA experiencing both jail incarceration and homelessness in 2001-03, 67% (N=782; **Temporary**) had sporadic experiences of brief jail incarceration and shelter stays over three years. About 13% of the study cohort exhibited trajectories characterized by shelter use patterns; one group spent extensive amounts of time in shelters (average 456 days) without much interruption, classified as **Continuously homeless** pattern (N=93), and the other had continuous shelter stays during earlier months followed by community-dwelling (**Decreasingly homeless**; N=56). The last two trajectory patterns included adults who were increasingly incarcerated during later months (**Increasingly incarcerated**; N=116) and those who had early incarceration events, followed by community-dwelling with sporadic incarceration (**Decreasingly incarcerated;** N=126).

Individuals with **Continuously homeless** pattern were older than those in other groups, while those with **Decreasingly incarcerated** pattern had a greater proportion of females (Table 4.1). Race/ethnicity, nativity, and neighborhood poverty appeared to be independent of trajectory groups. Approximately half of the study cohort across all trajectory groups had an indication of substance use, while prevalence of serious mental illness was highest in the **Continuously homeless** group. Individuals charged with drug possession, drug sales, property, and violent

crimes were more likely to exhibit the **Increasingly incarcerated** trajectory compared to those with other criminal charges. Age at HIV diagnoses and stage of HIV infection were similar across trajectory groups.

Among the study cohort, 48% had at least two HIV lab tests for viral load or CD4 counts, which were three months or greater apart during one-year follow-up time (Table 4.3). Prevalence of successful retention in HIV care was similar across all trajectory groups, ranging from 44% to 52%. When non-incarcerated/non-sheltered NYC PLWHA who were diagnosed with HIV and survived prior to 2004 were examined as a comparison group, a similar pattern was identified: 50% experienced retention in HIV care. During June 2005-June 2006, about 50% of the study cohort had viral load tests reported to the NYC HIV registry. Of these, 47% experienced viral suppression; prevalence of viral suppression was highest among individuals who stayed in shelters during the early months and dwelled in the community afterwards (**Decreasingly homeless**). During the same period, higher prevalence of viral suppression was observed among non-incarcerated/non-homeless NYC PLWHA (66%).

The marginal structural regression analysis shows that trajectories of jail incarceration and homelessness in 2001-03 were not significantly associated with prevalence of HIV care retention in June 2005-June 2006 (Table 4.4). Among NYC PLWHA who had viral load records and recent histories of jail incarceration and homelessness, those with **Temporary** relative to **Decreasingly homeless** patterns had 0.71 times lower prevalence of viral suppression during the same one-year period (95% Confidence Interval (CI) = 0.54, 0.93).

Results from the sensitivity analysis in Figure 4.2 show how the upper bound of 95% CI for the prevalence ratio for viral suppression could be affected by adjusting for unobserved confounding. As long as association between unobserved behaviors and viral suppression were greater than 1, $\delta > 1$ (i. e. , prevalence of unobserved behaviors among individuals with **Temporary** pattern is higher than that among those with **Decreasingly homeless** pattern) would have moved the upper bound of 95% CI away from 1. On the other hand, if particular behaviors among individuals with **Temporary** relative to **Decreasingly homeless** patterns were 20% less prevalent ($\delta = 0.8$) and association between these unobserved behaviors and viral suppression were strong ($PR \geq 2$ or $\gamma \geq 2$), the estimated prevalence ratio would have been insignificant.

Another sensitivity analysis showed that each of incarceration-only and homelessness-only populations with HIV/AIDS had four unique trajectories similar to those among the whole populations (Figure 4.3; Figures 2.3 and 2.4 in Chapter 2). Overall 45% of these two populations, similar to that of the study cohort, experienced retention in HIV care during the one-year followup time. Of those with any viral records, 48% (incarceration-only) and 54% (homelessness-only) had at least one lab test result of viral suppression (Table 4.5). The marginal structural regression analysis showed that among homelessness-only PLWHA the **Temporary** relative to **Decreasingly homeless** patterns had 0.77 times lower prevalence of retention in care during the same one-year period (95% CI = 0.65, 0.90; Table 4.6). In contrast, the **Temporary** pattern of incarceration in 2001-03, as opposed to the **Decreasingly incarcerated** pattern, was significantly associated with higher prevalence of HIV care retention among incarceration-only PLWHA (Table 4.7). Unlike the study cohort, prevalence of viral suppression was not associated with trajectories among the incarceration-only and homelessness-only populations.

4.4. Discussion

In this study, almost half of NYC adults living with HIV/AIDS who were sheltered and incarcerated in 2001-03 experienced retention in care during the one-year follow-up period. This percentage was similar between the incarcerated/homeless study cohort and nonincarcerated/non-sheltered NYC PLWHA who were diagnosed and alive prior to 2004. Unlike retention in HIV care, however, overall prevalence of viral suppression among those with viral load records was much lower among the incarcerated/homeless study cohort relative to nonincarcerated/non-sheltered NYC PLWHA, indicating relatively poor adherence to HIV treatment in the study population.

Similar to the finding in Chapter 2, a majority of the study cohort experienced brief bouts of jail incarceration and homelessness in 2001-03, and a minority was more consistently incarcerated or sheltered throughout the period of early or late months. Those who sporadically experienced brief jail incarceration and homelessness in 2001-03 were less likely to experience viral suppression during the one-year follow-up period compared with those who left homeless shelters during early months and persistently stayed in the community, whereas trajectory groups were independent of retention in HIV care.

The null association between trajectories of incarceration/homelessness and retention in HIV care did not support the hypothesis that frequent transitions of short-term jail incarceration and homelessness are associated with lower likelihood of continuity of care than a pattern of

persistent homelessness or incarceration. This lack of variability, coupled with similar prevalence of retention in care between the study cohort and non-incarcerated/non-sheltered

NYC PLWHA, implies that those with incarceration and homeless events were able to receive HIV care with recommended intervals. Since affordable HIV medical services and various social services were widely available through the Ryan White program and promoted in NYC neighborhoods, jails, and homeless shelters, experiencing life disruption due to jail incarceration and homelessness might not act as a barrier to making medical visits for those connected to care.[11]

Unlike retention in care, prevalence of viral suppression significantly differed by trajectories of incarceration and homelessness. This implies that adequate adherence to treatment might be worse among a group of PLWHA with sporadic exposure to brief jail incarceration and homelessness, compared with those who left shelters during early months and persistently stayed in the community afterwards. Given that access to permanent housing and services was available to NYC PLWHA, this positive finding among the reference group might result from effective case management that assisted them in adhering to HIV treatment regimens, which has previously been found beneficial.[4] Another possible mechanism is that being persistently out of shelter and jail is indicative of housing stability, creating a positive psychological influence on following medical treatments.[3] Data about housing and case services are warranted to test which mechanism is more probable.

The study finding supported the earlier interpretation that excess risk of HIV mortality associated with **Temporary** pattern is a manifestation of disruptions to HIV treatment due to transitions

between jails and shelters. In the current study, viral suppression may act as a mediator of the **Temporary** pattern-HIV mortality association. Sporadic experiences of brief jail incarceration and homelessness, as opposed to undisrupted community-dwelling, may contribute to elevating HIV mortality risk among NYC PLWHA with recent incarceration and homelessness by creating environments where essential HIV cares and adherence get disrupted. Future studies that link mortality data with HIV surveillance registry data are warranted to further explore and test mechanisms that explain excess HIV mortality risk associated with a pattern of sporadic exposure to brief jail incarceration and homelessness.

The sensitivity analysis showed that the overall association between trajectory groups and HIV continuity of care outcomes among the study cohort was not replicated in incarceration-only and homelessness-only PLWHA. While we observed no association between trajectories groups and retention in care among those in the main cohort, homelessness-only PLWHA who initially stayed in shelters then remained shelter-free (**Decreasingly homeless** pattern), compared with those with **Temporary** pattern, were more likely to be retained in care. In contrast, incarceration-only PLWHA with **Decreasingly incarcerated** pattern was least likely to have HIV care retained. It is possible that homelessness-only PLWHA who left shelters after brief stays, as opposed to prolonged stays, are less likely to get connected to the well-established housing services/programs.[20] For incarceration-only PLWHA, as a recent paper pointed out,[21] transition to stable community-dwelling from jail stays appeared to be more challenging than that among homelessness-only PLWHA during early 2000s, which could disrupt continuity of HIV care. For the main cohort, the null finding implies that staying in two different institutions increases chances for lab tests. In addition, unlike the main finding where prevalence of viral suppression

significantly differed by trajectories, viral suppression was not associated with homelessness or incarceration patterns in these populations. Proportions of incarceration-only (44%-58%) and homelessness-only PLWHA with any viral load records (59%-61%) were smaller than those in the main study cohort (58%-73%). Lack of variability of viral suppression experiences in these populations, coupled with these lower percent of having any viral load records, might reflect selection bias towards those with a high likelihood of adhering to HIV treatment. More detailed baseline data are warranted to test evidence of this selection bias.

This study has some limitations. First, there were limited data about demographic, behavioral, and clinical characteristics of PLWHA who were both incarcerated and sheltered. Individuals with **Temporary** pattern may be more likely to have high risk profiles than those with **Decreasingly homeless** pattern, or high risk profiles may be less prevalent among those with **Temporary** relative to **Decreasingly homeless** patterns. Depending on the direction of unobserved confounding between these patterns, the relationship between viral suppression and **Temporary** pattern could be biased either toward or away from the null, as seen in the sensitivity analysis. For example, suppose that 50% of individuals with **Temporary** pattern are non-injecting drug users. If the percent of non-injecting drug users among **Decreasingly homeless** individuals were 63% and non-injecting drug users were two times or higher more likely to experience viral suppression, **Temporary** versus **Decreasingly homeless** pattern would have been no longer significantly associated with viral suppression. Second, data about housing and housing services were not collected. Even though homeless PLWHA in NYC have a legal right to be housed, being out of shelter and jail does not necessarily mean being stably housed in the community. Lastly, viral suppression was defined as <400 copies/ml, which is different from a

current US Department Health and Human Services guideline (≤ 200 copies/ml).[22] Due to confidential concerns, raw viral suppression records were not provided and were dichotomized at 400 copies/ml, which was a widely adopted definition of viral suppression during mid-2000s. Additionally, association between trajectory groups and viral suppression was only assessed among those with at least viral load tests. If having any viral load tests were dependent of particular characteristic, selection bias could not be ruled out.

Despite these limitations, a main strength of the study is the use of a measure that captured dynamic aspects of jail incarceration and homelessness, potentially reflecting differing levels of housing instability. In addition, use of IPTW allowed for explicitly testing causal assumptions, further strengthening internal validity of the finding. Lastly, administrative data provided almost complete coverage of HIV care information provided to PLWHA in NYC.

In conclusion, sporadic exposure to brief jail incarceration and homelessness, relative to undisrupted community-dwelling after persistent shelter stays, was negatively associated with viral suppression among NYC PLWHA with recent incarceration and homelessness events. The study suggests that life disruption due to jail incarceration and homelessness does not appear to introduce additional barriers to receiving HIV care at recommended intervals but may exert negative physical and psychological influences on adhering to HIV treatment or receiving quality care, which is in turn related with low quality of life and survival. It also highlights the success of the reference group (i.e., high prevalence of viral suppression) who might experience stable community-dwelling for a relatively longer period. This finding justifies public health actions for housing stability through proactive case management and affordable housing options among

incarcerated and sheltered PLWHA in order to reduce risk of adverse health conditions and premature death.

Table 4.1. Demographic and criminal characteristics by five trajectory groups among 1,173 adults living with HIV/AIDS who were incarcerated in New York City jail and spent at least one night at New York City single adult shelter in 2001-2003

	NYC PLWHA§	Total	Temporary	Increasingly incarcerated	Decreasingly incarcerated	Decreasingly homeless	Continuously homeless

25-49 years	81%	84%	84%	86%	80%	89%	85%
50+ years	10%	7%	7%	3%	10%	7%	8%

Stage of HIV infection							
Early (HIV only)	96%	97%	97%	98%	97%	96%	95%
Late (HIV/AIDS)	4%	3%	3%	2%	3%	4%	5%

Notes: Bivariate associations between trajectory groups and criminal charges with drug possession, drug sales, violent crimes, property crimes, or public administration were statistically significant. Also, bivariate associations between trajectory groups and proxy measure of substance use or proxy measure of serious mental illness were statistically significant.

Average numbers of homelessness events were significantly different across trajectory groups except for Decreasingly incarcerated vs. Increasingly incarcerated and Temporary vs. Decreasingly incarcerated patterns.

Average numbers of jail days or incarceration events were significantly different across trajectory groups except for Temporary vs. Continuously homeless, Temporary vs. Decreasingly homeless, and Continuously homeless vs. Decreasingly homeless patterns.

Average numbers of homelessness days were significantly different across trajectory groups except for Temporary vs. Increasingly incarcerated, Temporary vs. Decreasingly incarcerated, and Increasingly incarcerated vs. Decreasingly incarcerated patterns. §Non-incarcerated/non-sheltered NYC residents living with HIV/AIDS.

†Because age was calculated at the end of year according to NYC HIV registry and raw birthdate information was not available, age of nonincarcerated/non-sheltered PLWHA was as of 12/31/2002.

††Because a small % of missing data (sex: 1%, race/ethnicity: 1%, nativity: 1%) in the study cohort were not included, sum of these numbers were not matched up with total numbers of individuals. For non-incarcerated/non-sheltered PLWHA, % of missing data were much greater than that among the study cohort.

¶Proxy measures were used to capture substance use and prior severe mental illness conditions.

Table 4.2. Mean within and between cluster distance ratios

Cluster number	Mean w/mean b	Δw/b		
2	0.526			
3	0.502	-0.024		
4	0.495	-0.007	5	**0.487** **-0.008**
6	0.483	-0.004		

Abbreviations: w = within-distance; b = between-distance; Δw/b = change in mean w/mean b
The optimal solution should meet two criteria: 1) mean within-distance/between-distance ratio < 0.50; 2) large decrease in mean within-distance/between distance ratio by increasing an additional cluster. Numbers in bold indicate the optimal solution according to these thresholds.

Chapter 5. Discussion

5.1. Overview of the dissertation

This retrospective cohort study of incarcerated/sheltered NYC adults aimed to create a longitudinal measure of exposure to jail incarceration and homelessness that reflected timing and sequencing of these events, and to test whether a particular trajectory contributes to risk of mortality or discontinuity of HIV care. Monthly experiences of jail incarceration, homelessness, and community-dwelling over three years were summarized into group-based trajectories using sequence analysis. For each trajectory group, baseline demographic, behavioral, and criminal

characteristics were described. Then, the study examined associations between trajectories of jail incarceration/homelessness and risk of all-cause, drug-related, and HIV deaths during the subsequent two years. The study further focused on the sub-set of the study cohort living with HIV/AIDS, and tested whether trajectories of incarceration/homelessness were associated with retention in HIV care and viral suppression. In the following section, the main findings and interpretations are summarized.

5.2. Summary of the findings

5.2.1. Chapter 2

Analysis of NYC adults with histories of both jail incarceration and homelessness during 2001-03 identified this group to be predominantly minority males aged to 25 to 44 years from poor NYC neighborhoods. This study cohort was sociodemographically similar to the population that only experienced incarceration in NYC jails during the same period,[1] except for a higher prevalence of substance use and property crimes. Compared with the NYC homeless population with no history of jail incarceration, the study cohort was disproportionately younger and male.

Sequence analysis identified six trajectory groups of incarceration/homelessness in 2001-03. A majority of the study cohort spent most time outside of jail and shelters and sporadically experienced brief jail incarceration and shelter stays. The remaining 40% had mixed experiences of homelessness and incarceration in various lengths and frequencies. Sporadic experiences of incarceration and homelessness with brief stays (denoted as the **Temporary** pattern), as opposed to the other patterns with persistent jail or shelter stays, appeared to be most consistent with the concept of the revolving door pattern, although the actual frequencies of incarceration or

homelessness events were small and the majority of time of these individuals was spent in the community. Sporadic exposure to incarceration and homelessness can generate life disruption, leading to elevated stress levels and interrupting continuity of essential health care. Another possible mechanism is that individuals with the **Temporary** pattern are neither stable and established in the community nor likely to benefit in a stable fashion from health care services in jails or shelters and receive proper discharge plans than those who stayed longer in these institutions.

For the purpose of the comparison, trajectories of incarceration or homelessness were also examined for NYC adults with jail incarceration-only and those with homelessness-only during 2001-03. In both populations, four trajectory groups were identified and a majority exhibited the **Temporary** pattern. Within similar trajectory groups across incarcerated or sheltered NYC populations, short and frequent experiences of incarceration or homelessness appeared to be more common among the study cohort who had dual exposures relative to single exposure. In addition, among the subset of incarcerated people with the **Temporary** trajectories, particular criminal characteristics such as property crimes and drug possession were more prevalent among those with both experiences as opposed to incarceration-only. High prevalence of property crimes may indicate material deprivation or financial stresses in this population,[2] but it may also reflect disruptive behaviors resulting from substance use or mental illness.

5.2.2. Chapter 3

During 2004-05, the age-adjusted all-cause mortality rate among NYC adults who were both incarcerated and sheltered in 2001-03 was similar to that among homelessness-only population,

but higher than in incarceration-only population. Focusing on the incarcerated and homeless population, mortality risk during 2004-05 was estimated for each of six trajectory groups of incarceration and homelessness, which were identified in Chapter 2. The SMR analysis found that all-cause mortality risk of the study cohort with sporadic exposure to brief jail incarceration and homelessness (i.e., **Temporary** pattern) was significantly higher than that of nonincarcerated/non-sheltered NYC adults of the same age, sex, race/ethnicity, and neighborhood poverty (SMR = 1.35). The SMRs for drug-related and HIV deaths among individuals with the **Temporary** pattern were 4.60 and 1.54, respectively. Compared with non-incarcerated/nonsheltered NYC adults, excess risk of drug-related deaths was also observed in the other trajectories except for one group with persistent shelter stays without much disruption (**Continuously homeless**) and the other with incarceration during later months (**Increasingly incarcerated**), whereas there was no significant difference in risk of all-cause and HIV mortality between the other trajectory groups and non-incarcerated/non-sheltered NYC adults. Similarly, after balancing out differences in baseline covariates across six trajectory groups, the

Temporary versus **Continuously homeless** patterns was associated with the elevated risk of allcause, drug-related, and HIV deaths.

Excess risk of all-cause mortality among incarcerated & sheltered adults with the **Temporary** pattern may indicate health burdens attributed to the revolving door pattern. One possible mechanism is that disruption of quality medical care due to transitions from brief incarceration or homelessness to community-dwelling exerts negative influences on health conditions. It may also explain the association between the **Temporary** pattern and high risk of HIV death because

continuity of antiretroviral care is critical for survival among people living with HIV/AIDS.[3] This mechanism is further discussed in the summary of Chapter 4 below.

Compared with non-incarcerated/non-sheltered NYC residents, all trajectory groups except for **Increasingly incarcerated** and **Continuously homelessness** patterns were associated with excess risk of drug-related death. Individuals who were incarcerated during later months or consistently stayed in homeless shelters in 2001-03 were more likely to remain incarcerated or sheltered during subsequent two years, which might decrease circumstances to use drugs. Unlike drug-related death, risk of HIV death was not elevated among NYC adults who had incarceration/homelessness sustained for certain time points. During uninterrupted stays, they might benefit from medical services or referrals offered in shelters or jail. Indeed, data in Chapter 4 support this interpretation as retention in care was comparable to that among nonincarcerated/non-sheltered NYC PLWHA. However, prevalence of viral suppression among the study cohort living with HIV/AIDS was lower than NYC prevalence, implying that receiving regular care did not necessarily mean receiving quality care nor adhering to HIV treatment.

5.2.3. Chapter 4

Among the study cohort, 1,173 were diagnosed with HIV/AIDS prior to 2004. Nearly half of these individuals experienced retention in care during June 2005-June 2006. This percentage was comparable to that of non-incarcerated/non-sheltered NYC PLWHA who were diagnosed and alive prior to 2004. Unlike continuity of HIV care, overall prevalence of viral suppression was much lower among the study cohort with viral suppression records relative to nonincarcerated/non-sheltered NYC PLWHA.

Similar to the finding in Chapter 2, a majority of the study cohort living with HIV/AIDS sporadically experienced brief jail incarceration and homelessness in 2001-03, while the rest was more persistently incarcerated or sheltered for early or late months. This measure was independent of retention in HIV care, but significantly associated with viral suppression during the one-year follow-up time. Specifically, those with **Temporary** versus **Decreasingly homeless** patterns had 0.71 times lower prevalence of viral suppression.

The null association between trajectory groups and retention in HIV care implies that the study cohort would be able to receive HIV care at recommended intervals. Since affordable HIV medical services and various social services were available and easily accessible at many different settings in NYC including jails, shelters, and deprived neighborhoods, experiencing life disruption due to jail incarceration and homelessness might not act as a barrier to medical visits for those connected to care.[4]

The significant association between prevalence of viral suppression and **Decreasingly homeless** pattern implies that those who left shelters early months and persistently stayed in the community afterwards were more likely to experience viral suppression, which might result from receiving quality HIV care or adequately adhering to treatment. In contrast, adequate adherence to antiretroviral treatment might not be achieved among a group of PLWHA whose communitydwelling was sporadically disrupted by incarceration and homelessness. Given well-established access to permanent housing and housing services for NYC PLWHA, this result may

be further attributed to effective case management.[5] It also indicates a potential psychological influence of housing stability on complying with medical treatments.[6]

The study finding in Chapter 4 supports the earlier interpretation that excess risk of HIV mortality associated with the **Temporary** (or revolving door) pattern would be a manifestation of disruptions of medical care due to transitions from/to jails and shelters. Sporadically experiencing brief jail incarceration and homelessness, PLWHA may be less likely to comply with HIV treatment, which in turn negatively influences health conditions. It seems a plausible mechanism that explains the **Temporary** pattern-HIV mortality association in Chapter 3. Future studies that link mortality data with HIV registry will be beneficial to understand direct and indirect pathways from the revolving door pattern to HIV mortality.

5.3. Limitations

This study has several limitations. First, a process of identifying groups of trajectories required a strong assumption that heterogeneity of trajectories is derived from latent groups, not an underlying continuous distribution such as life course development of IQ, psychological attributes, and employment.[7] This assumption seems plausible because being homeless or incarcerated is a major life disruption and the policy convention recognizes unique groups of homeless adults such as chronic and episodic homelessness.[8] Empirically, the current trajectory groups of the study cohort represent unique experiences of jail incarceration and homelessness. Yet, more research is still warranted to reinforce theoretical and empirical support for groupbased trajectory modeling approach to describe longitudinal exposure to incarceration and homelessness. Second, the study used aggregate data to assess mortality risk among

nonincarcerated/non-sheltered NYC adults. Thus, inference from the SMR analysis in Chapter 3 should be made with caution because the estimated relative risk could be biased due to residual confounding. Third, homelessness, jail incarceration, and residing in the community were determined according to NYC single adult shelter use and NYC jail admission/discharge dates, which might underestimate true incarceration/homelessness events (e.g., street homelessness, incarceration outside of NYC). This bias, however, may be counterbalanced by overestimation of true community-dwelling, and improved validity and reliability of measures from administrative data as opposed to self-reports. In addition, death outcomes were likely to be underestimated because deaths outside of NYC were not captured in this study. The estimated relative risk for mortality is likely to be biased toward the null if this measurement error is independent of trajectory groups. Fourth, matched data from multiple registries did not contain much information about risk behaviors and clinical antecedents of excess mortality and morbidity risk. Even if the results from the sensitivity analyses assured excess mortality risk associated with the **Temporary** pattern, unknown factors that might explain the observed association cannot be completely ruled out. Fifth, the analysis was only based on study participants who used NYC shelters or jails and survived in 2001-03. This may introduce a survivor bias by conditioning on a collider. The excess drug-related mortality risk among the **Temporary** (the exposed) versus **Continuously homeless** groups (the unexposed) was attenuated and non-significant after adding early death cases. It may reflect the younger ages of early drug-related deaths among the unexposed, or the study design that no actual treatment was not provided to the exposed. Longer follow-up time is required to determine presence of survivor bias because 1) the sensitivity analysis result is based on a very small number of drug-related deaths; 2) trajectory grouping among early deaths is based on the two-year exposure period on average and may not be reliable.

Lastly, two years may not be a sufficient time to assess mortality risk due to chronic diseases. Long-term health impacts of some trajectories other than the revolving door pattern may be different from those observed for two immediate years.

5.4. Strengths and public health significance

There are a number of strengths in this study. First, by studying a large and representative sample of adults with both jail incarceration and homelessness, this study contributed to expanding descriptive data and a general understanding of the magnitude and nature of the 'revolving door' problem from a public health context. In particular, the use of the combined registry records allowed for identifying various trajectories of jail incarceration/homelessness, as seen in Chapter 2. Second, by linking these trajectories with baseline characteristics and health outcomes, the study yielded more complete profiles of demographic and criminal characteristics and risk of mortality and morbidity for adults cycling through jails and homeless shelters, compared with previous cross-sectional studies. It also allowed for testing a dose-response relationship between trajectories of jail incarceration/homelessness and health outcomes where the **Temporary** (or revolving door) pattern was considered as the highest dose.

Methodologically, the main strength of this study is an innovative approach to improve construct and internal validity of administrative data. First, using sequence analysis, temporal sequences and timing of jail incarceration and homelessness events were summarized into distinct groups of individuals. Compared with commonly-used simple indicator or time-aggregated measures of each event,[9,10] this approach allowed for more explicitly capturing potential life challenges associated with experiences of incarceration/homelessness.[11] For example, the current measure

identified a group with more frequent exposure to the vulnerable time after release from jail, which might have been collapsed with those with less exposure if sequencing of events were ignored. For PLWHA, trajectory groups of incarceration/homelessness are likely to be indicative of housing disruption because of their legal right and support to obtain permanent housing in NYC. Second, this study makes an important contribution to epidemiologic research by demonstrating analytic approaches to estimate causation from administrative data, which is challenging because of non-random exposure assignment and limited data about potential confounders. Existing studies tend to report associations adjusted for a small number of demographic variables, which may be insufficient to rule out influences from bias due to other confounders, selection, and measurement errors. In this study, violation of casual assumptions and confounding due to unobserved confounding were addressed via IPTW and sensitivity analyses. Specifically, by weighting the exposure-outcome relationship by an inverse of propensity score, differences in observed baseline characteristics across trajectory groups were controlled, meeting exchangeability assumption. Additionally, IPTW was tightly distributed around 1, justifying no adjustment to meet positivity asumption.[12] The potential violation of the stable unit treatment value assumption was also addressed by adjusting the estimates by poverty levels of neighborhood residency. Regarding bias due to unobserved confounders, the study performed sensitivity analyses and quantified the extent to which observed associations might be biased from causal association.

5.5. Policy recommendations and future research directions

This study provides important evidence that structural exposure to incarceration and homelessness contributes to adverse health conditions even after controlling for individual-level

risk factors. In general, individuals with both incarceration and homelessness had higher risk of all-cause and HIV mortalities, compared with those with incarceration-only and homelessnessonly, even if sociodemographic characteristics appeared to be similar across these three populations. Furthermore, after controlling for potential confounders, mortality risk was associated with distinct trajectories of incarceration and homelessness. These study findings justify allocating more resources to target a group of individuals characterized by their experiences of incarceration and homelessness (e.g., brief versus long-term stayers) rather than individual behaviors or demographics. Currently, NYC DOC administers a wide range of jailbased public health services including substance use disorders counseling, mental health screening and therapy, and opioid maintenance treatment.[13] Similarly, shelter entrants in NYC are required to fill out a screening form, which allows NYC DHS to make an initial assessment on mental and physical health conditions and provide services or referrals to shelter users.[14] During shelter stays, various social services including employment and housing are available, while follow-up referrals are provided upon discharge from shelters. Due to excess mortality risk associated with the **Temporary** pattern, these jail- and shelter-based programs should be expanded for more proactive engagement with individuals who briefly stay in jail or shelter, aiming to promote risk of overdose death and medical treatment options during and after jail/shelter stay. In particular, given high risk of drug-related death after release, NYC DOC and DHS should continue to collaborate with community organizations to strengthen communitylinkage services such as maintaining drug counseling/therapy and providing supportive housing with drug treatment services, as these have been effective in reducing overdose risk factors at both individual and environmental levels.[13]

For PLWHA, the finding supports the importance of discharge planning[15] and housing stability for health improvement.[16] For those cycling through shelters and jails, providing medical services at various settings may not be sufficient to improve health conditions. Social services that assist activities of daily living and stable lives may also play a crucial role in promoting quality of life and health conditions, as evidenced in the previous and current studies.[5] In NYC, a wide array of medical and social services are available for PLWHA, and further efforts such as outreach activities should be made to help them connected to these essential services to reduce recidivism and improve housing stability.[4] One recent example is Transitional care coordination program targeted for incarcerated PLWHA.[15] In 2006, this program was launched in order to integrate disorganized linkage services in NYC jail and improve transition to the community. Specifically, the program developed a holistic service delivery structure that emphasizes proactively tracking clients through jail-and community-based coordinators and electronic health records. Once PLWHA were identified during the jail intake, they were contacted at the first day of incarceration for HIV treatments. After this initial contact, incarcerated PLWHA were followed up at various time points during and after release to develop discharge plans and ensure connection to medical and social services in the community.

In conclusion, the study revealed six unique groups of trajectories of jail incarceration and homelessness among 15,620 adults who stayed for at least one night in NYC jails and NYC single adult shelters in 2001-03, and each group represented unique timing and sequencing of these events and life challenges. Among these trajectory groups, sporadically experiencing brief jail incarceration and homelessness was associated with excess risk of all-cause, drug-related, and HIV deaths. For the subgroup of the study cohort living with HIV/AIDS, this pattern was

associated with lower prevalence of viral suppression, compared with a pattern of prolonged shelter-free and jail-free period. These findings provide evidence for unique contribution of structural exposure on mortality and morbidity risk in this vulnerable population. Along with behavioral interventions, efforts to modify patterns of incarceration/homelessness experiences may be equally important to reduce risk of adverse health conditions. This study calls for further research and discussion to identify more refined mechanisms that explain association between longitudinal incarceration/homelessness experiences and mortality/morbidity, which leads to practical actions and policies for system-wide changes.

Appendix I. Baseline demographic and criminal characteristics before and after inverse probability of treatment weighting by trajectory groups among 15,620 adults who were both incarcerated and sheltered during 2001-03

Serious mental illness	2%	4%	6%	2%	6%	9%
Serious mental illness (weighted)	4%	3%	3%	3%	3%	4%

Appendix II. Summary of inverse probability of treatment weight

	Mean	Std	Min	Max
All-cause and drug-related mortality model	0.996	0.324	0.164	4.125
HIV model	0.997	0.302	0.246	3.818

Abbreviations: std, standard deviation.

Appendix III. Two-by-two table of actual and imputed neighborhood poverty variables among randomly selected 25% of the complete data

	Imputed neighborhood poverty (row %)				
Actual neighborhood poverty	Low	Medium	High	Very high	Total
Low (<10% below poverty)	3539 (78%)	361 (8%)	199 (4%)	463 (10%)	4562
Medium (10% to <20%)	356 (1%)	25841 (83%)	1362 (4%)	3682 (12%)	31241
High (20% to <30%)	219 (1%)	1424 (7%)	15037 (79%)	2441 (13%)	19121
Very high (≥30%)	485 (1%)	3839 (6%)	2428 (4%)	55706 (89%)	62458

Notes: Simple kappa = 0.76 (95% CI = 0.76, 0.77), weighted kappa = 0.77 (95% CI = 0.77, 0.77).

Appendix IV. Baseline demographic and criminal characteristics before and after inverse probability of treatment weighting by trajectory groups among 1,173 adults living with HIV/AIDS who were both incarcerated and sheltered during 2001-03 and had viral load reports in 2004-05

	Temporary	Increasingly incarcerated	Decreasingly incarcerated	Decreasingly homeless	Continuously homeless
Total	525	73	88	42	59
Age as of 6/30/2002					
18-24 years	29%	30%	26%	17%	25%

The association of individual characteristics, perceived neighborhood social cohesion, and neighborhood poverty with achievement of HIV viral suppression among persons recently diagnosed with HIV and interviewed in New York City

Introduction

More than 40,000 persons in the United States (US) are diagnosed with HIV each year, of whom more than 3,000 are in New York City (NYC).[1, 2]. Federal guidelines recommend that persons with HIV have their viral load (VL) measured as soon as they begin HIV-related medical care after diagnosis and at least every six months thereafter.[3] HIV infection typically is followed by a very high VL (e.g., >100,000 copies of HIV RNA per milliliter of blood) that eventually declines to a lower set point that varies by individual and individuals' characteristics. Further reduction of HIV VL to levels that are low or undetectable (e.g., ≤400 copies/mL) is called viral suppression. Although a small percentage of persons is able to suppress virus without treatment (i.e., elite controllers), most persons suppress by being treated with combination antiretroviral therapy (ART).[4] Provided that the virus is sensitive to the multi-drug regimen chosen and the person is adherent, ART suppresses virus quickly (within 24 weeks) and durably.[5, 6]

Viral suppression not only slows progression of HIV disease [7] but also reduces the likelihood of onward sexual transmission.[8] The US National HIV/AIDS Strategy set as a goal a 20% increase by 2015 in the proportion of persons in populations most affected by HIV (blacks, Hispanics, and gay and bisexual men) who are virally suppressed.[9] Updated national HIV treatment guidelines now recommend that all persons with HIV be offered ART, although until recently, it was recommended that persons begin ART only once immunocompromised.[3] Although retention in care and ART are the main drivers of viral suppression, more rapid achievement of suppression has also been associated with individual-level demographic characteristics, e.g., older age,[10-12] male sex,[13-15] non-black race [10, 16-20], and baseline clinical status indicators such as higher? CD4 count and lower? VL.[12, 21, 22]

Studies focusing on individual-level factors affecting viral suppression may benefit from the addition of social and structural variables, such as perceived neighborhood social cohesion and neighborhood-level socioeconomic status. Lower perceived neighborhood social cohesion has been associated with lower primary care use among older urban adults[23] as well as lower condom use and

higher sexually transmitted infection (STI) rates among urban adolescents and young adults.[24, 25] The time from HIV diagnosis to viral suppression may be influenced by care-seeking behavior because ART and VL testing are offered exclusively in the context of medical care visits. Suppression may be influenced by condom use and STI rates because STI infection can increase VL. However, the association of social cohesion with HIV outcomes has not been explored. Neighborhood social cohesion is typically measured by responses to a scale that includes several interview questions (refs?), and we had the unique opportunity to do use a validated scale? for a random sample of New Yorkers recently diagnosed with HIV. Lower neighborhood-level socioeconomic status has been associated with higher rates of diagnosis of HIV or AIDS, delayed access to treatment, and mortality, at both the individual and neighborhood level.[26-33] For example, in a US city, HIV-positive residents of higher-unemployment neighborhoods were less likely to be on ART, thus reducing their likelihood of achieving suppression.[33] Moreover, in a province of Canada, a country with universal health care and free HIV treatment, after controlling for clinical characteristics, residents of lower-SES neighborhoods (as measured by median income) were less likely than residents of higher-SES neighborhoods to be prescribed the particular ART regimen that was the standard of care.[27] Thus, neighborhood SES has been shown to have an effect on ART use in some settings; this association has not been explored to date in NYC.

Commented [HJ1]: Which city? IF this is NYC than do we know the answer already?

We investigated the effect of individual characteristics, perceived neighborhood social cohesion, and neighborhood-level poverty on achievement of viral suppression, among NYC residents who were diagnosed with HIV between 2006 and 2012 at ≥13 years of age. You need to add a sentence or two about why it matters – e.g. – if neighborhood factors play a role in ability to achieve viral suppression, then what? What is the public health significance?

Methods

Data sources

This retrospective analysis used data from the NYC HIV surveillance registry, the NYC arm of the CDC-coordinated Case Surveillance-Based Sampling project (CSBS),[34] the 2010 US Census,[35] and the 2011 American Community Survey.[36] The registry includes all persons diagnosed and reported with HIV in NYC since 2000. It gathers information by medical record review, provider report at diagnosis, and HIV-related laboratory tests, which are electronically reported to surveillance for all existing cases

receiving diagnosis and/or care in NYC. Individual-level data acquired from the registry included demographic and clinical information collected at the time of first report, ZIP code of residence at diagnosis, and HIV-related laboratory test results from January 1, 2006, to June 30, 2014. Laboratory reports contain the test type, specimen collection date, result, and submitting facility. Reports on existing cases are added to their surveillance registry record; reports that do not match to an existing case are initiated for field investigation to confirm the diagnosis and collect other registry data. All registry data were reported as of September 30, 2014.

Data from CSBS included individual-level information on household income, number of persons who depended on that income (a proxy for household size), highest educational level completed, and three questions that were aggregated to develop an index of perceived neighborhood social cohesion. CSBS data were from the interview portion of the 2012-2014 cycles of the study and reported by April 15, 2015. Finally, neighborhood data at the level of ZIP code tabulation area (ZCTA) were acquired from the 2010 US Census and the 2011 American Community Survey 5-year estimates. ZIP codes are a system of delineating areas for postal service, and most people know the ZIP code of their residence, while ZCTAs are geographic areas used by the Census and ACS as close geographic approximations of ZIP codes.[37] ZIP codes, which in NYC are typically larger than Census tracts but smaller than congressional districts and counties, were the smallest readily available geographic unit of analysis. Neighborhood data were linked to cases through the ZIP code of patient residence at time of first diagnosis?.

Commented [HJ2]: And an interview? How does this relate to the paragraph below?

Commented [HJ3]: Confused how this relates to the lab results through June 30 listed above.

Commented [HJ4]: Where did these questions come from? Has this index been used before?

Commented [HJ5]: What is this?

Commented [HJ6]: Again, how does this relate to the June 30 and September 30th dates above?

Population

NYC residents who were newly diagnosed with HIV between 2006 and 2012 at ≥18? years of age and who were interviewed for CSBS were eligible for the analysis. CSBS selected a random sample of XXX persons ≥18 years of age from the HIV surveillance registry for each of three years (2012-2014), stratified by time period of diagnosis. The 294 persons located and interviewed for CSBS in 2012-2014 were excluded if they: were not newly diagnosed with HIV between 2006 and 2012 at ≥13 years of age (n=152), did not have an NYC ZIP code of residence at diagnosis (n=9), did not have a Western blot confirmatory test within 31 days post-diagnosis *and* were not diagnosed during acute HIV infection (i.e., their true diagnosis date was uncertain; n=6), had a suppressed (≤400 copies/mL) viral load ≤31 days

Commented [HJ7]: How many people?

Commented [HJ8]: So does not include 13-17 year olds, right?

Commented [HJ9]: Year? Quarter? Month?

Commented [HJ10]: 18 or 13?

after diagnosis which therefore suggested a misclassified diagnosis date (n=11), or did not respond to all three questions about perceived neighborhood social cohesion (n=24). These exclusions yielded an analytical sample of 92 persons (see Appendix 5).

Commented [HJ11]: This is for the social cohesion analysis – but you have more data points for low SES, no?

Outcome

The outcome of interest was the first VL test after HIV diagnosis that indicated suppression (≤400 copies of HIV RNA/mL plasma). The cut-off was 400 copies/mL because this was the highest lower detectable limit of VL assays in use during the study period.[38] Censoring occurred at death or the end of the follow-up period, whichever came earlier. Follow-up time was calculated as the number of days from the date of HIV diagnosis to suppression, death, or 6/30/2014, whichever came first.

Commented [HJ12]: Ok -so make clear above how the end date of data collection occurred.

Commented [HJ13]: Was everyone followed for a minimum of 6 months? 12 months?

Although treatment guidelines recommend VL tests at certain intervals after HIV diagnosis, some persons with HIV may have infrequent or no VL tests after diagnosis, because they were never linked to HIV-related medical care, they seek care infrequently, or their physician does not test their VL at every care visit. Persons who were not known to be dead and who had no suppressed VL (including persons with infrequent or no VL tests) were presumed not to be suppressed and contributed follow-up time as long as they were alive.

Commented [HJ14]: How many people are in this category from the 92?

Covariates

Demographic characteristics (age, sex at birth, race/ethnicity, area of birth), HIV transmission risk (also referred to as transmission categories), diagnosis date, viral loads, CD4 counts, estimated poverty status, perceived neighborhood social cohesion, and ZIP code of residence at diagnosis were extracted from the NYC HIV surveillance registry and CSBS. Age at HIV diagnosis was calculated from birth date and date of diagnosis and categorized as 13-29 and 30+.[2] Sex at birth was classified as male or female. Race (white or Caucasian, black or African American, Asian or Pacific Islander, and Native American) and ethnicity (Hispanic, non-Hispanic, or unknown) were collected through two questions and combined into a single variable that was dichotomized as: black or Hispanic, and other for those of other race/ethnicity. Country of birth was collected as country of birth when available or region of birth and categorized as born in the US or a US dependency (e.g., Puerto Rico), or a foreign country. HIV transmission risk category was based on the self-reported pre-diagnosis risk behaviors of the case (e.g., injection drug use, male-male sex) and the sex, HIV status (e.g., HIV-positive), and risk (e.g., injection

Commented [HJ15]: I would clarify and start with your main exposures of interest – if they were your main exposures as described in the introduction – and talk about neighborhood social cohesion and neighrohood poverty. This section does not erally match the set up in the intro – hard to know what you are testing and what your hypotheses are.

Little unclear if you are thinking of these neighborhood factors as exposures of intereset, in which case you want to justify inclusion of individual characteristics as potential confounders – or whether you are thinking of this as a predictive model so want to see if your model fit improves when you add neighborhood level variables.

Commented [HJ16]: Country? Region?

drug use) of the pre-diagnosis heterosexual-sex partners that s/he reports (which could indicate high-risk heterosexual risk).[39] This information was combined into hierarchical, mutually exclusive categories for the case: injection drug use (IDU), men who have sex with men (MSM), heterosexual sex, and other or unknown (which included perinatal transmission),[12] and these categories were then combined into three final groups: MSM, heterosexual, or other or unknown. To be classified as a heterosexual male or female, persons must have reported pre-diagnosis sex with a partner of the other sex who was HIV-infected, had injected drugs, or had received blood products. In addition, females only could be classified as heterosexual if they had probable heterosexual transmission noted in their medical record, reported sex with a male and not have injected drugs, or had any one of several behaviors associated with heterosexual transmission: history of prostitution, multiple sex partners, sexually transmitted disease, crack/cocaine use, or sex with a bisexual male.[2] For analytic purposes, the year of diagnosis was determined from the earlier of physician diagnosis date or positive Western blot test result and grouped as 2006-2009 and 2010-2012. CD4 count (if any) at diagnosis (i.e., within 3 months of diagnosis) and year of diagnosis vis-à-vis treatment guidelines were used to estimate treatment eligibility and as a proxy for receipt of ART, on the presumption that the majority of persons reaching the federal treatment threshold would receive ART. Treatment-eligible persons included those diagnosed in 2006-2007 with CD4<200, diagnosed in 2008-2009 with CD4<350, or diagnosed in 2010-2012 with CD4<500, reflecting changing treatment guidelines that increased the CD4 count at which ART initiation was recommended.[40-42] All other persons were not known to be eligible and were classified as not eligible. Estimated poverty status was calculated based on responses in CSBS to questions about household income (which was collected as a range) and number of persons who depended on that income. These were compared with US Census Bureau weighted average poverty thresholds for 2013 by size of family unit, and then classified as below the threshold (and thus “non-poor”) or above (“poor”).[43] Perceived neighborhood social cohesion was calculated from responses to three questions about trust, closeness, and helpfulness between neighbors using a scored 1-4 Likert scale. [24, 25] Responses were summed, and these sums of 3-12 were dichotomized at a natural break that would place approximately equivalent numbers of persons in each category.[25] Specifically, the majority of sums were 6, 9, or 12 (>20% each), and 48% of persons had sums of 3-8. Lower scores indicated agreement with positive statements

Commented [HJ17]: What happened to IDU?

Commented [HJ18]: Why did you group them like this?

Commented [HJ19]: Given this distinction, not clear why 2006-7 was combined with 2008-9?

about the neighborhood; perceived neighborhood social cohesion was classified as high for persons with sums of 3-8 and low for persons with sums of 9-12.

Analyses included percent of residents in a ZIP code with incomes under the federal poverty threshold, from 2011 American Community Survey (ACS) 5-year estimates because the 2010 decennial census did not collect poverty information.[44] This poverty measure has been associated with HIV and sexually transmitted infections.[26, 27, 29, 30, 45, 46] Poverty was dichotomized as <20% (low or medium poverty) or ≥20% (high or very high poverty), based on a four-category recommendation of the NYC health department that was collapsed into two categories.[47]

Commented [HJ20]: Do you mean with risk of acquiring these infections or with management and treatment of them or both? Is this in NYC or in the US?

Statistical analysis

Descriptive statistics for selected individual and neighborhood characteristics were calculated and presented for the overall population and according to suppression status within 12 months of diagnosis. Significance of associations between each variable and achievement of suppression within 12 months was assessed using Chi-square tests. The Mann-Whitney U test was used to ascertain differences in median days to suppression by the end of follow-up.

Commented [HJ21]: You need to explain that this is one way you looked at your outcome when you describe the outcome above.

Kaplan-Meier curves showing the number of days from diagnosis to suppression were generated by key individual and neighborhood characteristics, and log-rank tests were used to indicate differences between groups.

Cox proportional hazards regressions estimated the association of individual and neighborhood factors with suppression in crude and adjusted models. Because of the small sample size, we did not account for correlations of individual outcomes within neighborhood (ZIP code).[48, 49] Unadjusted models were fitted to estimate the unadjusted hazards of viral suppression for each individual and neighborhood characteristic. In addition, a series of multivariable models were fitted, striving for parsimony given the small sample size. Our final model included age at HIV diagnosis, sex at birth, race/ethnicity, year of HIV diagnosis, and ART eligibility, for consistency with previous models of viral suppression,[12] as well as perceived neighborhood social cohesion and neighborhood-level poverty.

Commented [HJ22]: Did you look to see how correlated these two variables were? If highly correlated not sure it makes sense to put both in the same model?

All analyses were conducted using SAS 9.2 (SAS Institute, Cary, NC). Ethical approval for these analyses was provided by the Institutional Review Boards of Lehman College of the City University of New York and of the NYC Department of Health and Mental Hygiene.

Results

Descriptive statistics

Of 92 New Yorkers newly diagnosed with HIV in 2006–2012 and interviewed by CSBS, approximately three-quarters were male (72.8%), and black or Hispanic (82.6%; Table 1). More than half were ≥30 years old (66.3%), born in the US or a US dependency (68.5%), MSM (51.1%), diagnosed in 2010-2012 (54.3%), not eligible to receive treatment based on CD4 count and diagnosis year (53.3%), poor (60.9%), perceiving low neighborhood social cohesion (52.2%), and residents of high- or very-high-poverty neighborhoods (57.6%).

Sixty-five percent of the population achieved suppression within 12 months of diagnosis (Table 1). Suppression rates at 12 months were lower among persons who were younger (45.2% of persons 13-29 years old achieved suppression vs. 75.4% of persons ≥30), black or Hispanic (59.2% vs. 93.8%), born in the US or a US dependency (57.1% vs. 82.8%), and not eligible for treatment (46.9% vs. 86.0%; all *p*-values<0.05). Similarly, compared with persons who suppressed within 12 months, those who did not were more likely to be younger (53.1% were 13-29 years old), black or Hispanic (96.9%), born in the US or a US dependency (84.4%), and not eligible for treatment (81.3%).

Almost the entire population (95.7%) achieved viral suppression by 6/30/2014 (not shown), in a median of 180 days (Table 1). Suppression happened least quickly among persons who were younger (377 days), black or Hispanic (203 days), born in the US or a US dependency (218 days), not known to be eligible for treatment (372 days), or who had low perceived neighborhood social cohesion (204 days; all *p*-values <0.05). Differences were most prominent by age (164 days among persons ≥30 years old vs. 377 days among 13-29) and treatment eligibility (159 days among eligible vs. 372 days among not eligible). Kaplan-Meier survival curves demonstrated the difference in achievement of suppression between persons eligible and not eligible for treatment (p=0.0003; Figure 1a), as well as the lack of difference between persons with low and high perceived neighborhood social cohesion (p=0.9541; Figure 1b) and residents of high- or very-high-poverty vs. low- or medium-poverty neighborhoods (p=0.4552; Figure 1c).

Unadjusted and adjusted models

Table 2 presents the unadjusted and adjusted HRs for HIV viral suppression among CSBS participants newly diagnosed with HIV in NYC. The unadjusted HRs show that persons who were black or Hispanic, born in the US or a US dependency, diagnosed in 2006-2009, or not eligible for treatment were at least 42% less likely to achieve viral suppression (range 42% to 60%) than their counterparts. Perceived neighborhood social cohesion and neighborhood-level poverty were not associated with suppression.

Multivariable regression included age at HIV diagnosis, sex at birth, race/ethnicity, year of HIV diagnosis, ART eligibility, perceived neighborhood social cohesion, and neighborhood-level poverty. After adjustment, the likelihood of viral suppression was 55% lower for blacks or Hispanics (95%CI=0.23-0.86) than persons of another race/ethnicity, and 42% lower among persons not eligible for treatment (95%CI=0.35-0.96) than treatment-eligible persons. Year of diagnosis, perceived neighborhood social cohesion, and neighborhood-level poverty were not associated with suppression in the fully adjusted model but were included given our interest in these factors. Compared with a model with variables for age at HIV diagnosis, sex at birth, race/ethnicity, year of HIV diagnosis, and treatment eligibility, this model (which added cohesion and poverty variables) did not have significantly better fit (-2LL: 617.2; p=0.6044; see Appendix 5).

Discussion

Controlling for individual characteristics, neighborhood poverty, and perceived neighborhood social cohesion, persons who were black or Hispanic and who were not eligible for treatment were less likely to achieve HIV viral suppression after diagnosis. Neighborhood poverty and perceived neighborhood social cohesion did not influence the time from diagnosis to viral suppression.

Consistent with a previous study using NYC HIV surveillance data.[12], we found that black race and not being eligible for treatment were associated with delayed suppression. Treatment eligibility and suppression were associated with each other presumably because treatment-eligible persons were more likely to have been prescribed ART, the primary means of lowering viral load. However, in contrast, findings for perceived neighborhood social cohesion and neighborhood characteristics were not consistent with previous findings on their relationship with care-seeking behavior and HIV and/or STI

outcomes.[23-33] As relates to cohesion, perhaps it is not associated with condom use, STIs, and care-seeking behaviors among persons with HIV in NYC, or there may be other factors that then prevent those from influencing time to suppression. For example, the system of care and services, comparatively generous benefits, and large HIV-positive population in NYC make it a relatively attractive place for HIV-positive persons to live and receive care, and may mitigate the influence of neighborhood cohesion or poverty. While neighborhood-level socioeconomic factors have been associated with HIV diagnosis rates in NYC and elsewhere, and some care-related outcomes,[26-32] in our analysis, neighborhood poverty was not associated with time to suppression once diagnosed. Several possible explanations include: different outcomes (e.g., time from ART initiation to suppression vs. time from diagnosis to suppression); different settings (e.g., Canada vs. US, or other US areas vs. NYC); HIV care is perhaps comparably accessible and effective regardless of characteristics of the NYC neighborhood in which people live, mitigating neighborhood-level disadvantage after diagnosis; publication bias may have limited the publication of previous null findings on neighborhood characteristics and HIV outcomes, so our findings may be consistent with some previous, unpublished analyses;[50, 51] and individual characteristics are more important than neighborhood characteristics in achieving suppression after diagnosis.

Commented [HJ23]: Could it also be that your study did not have sufficient power to detect an effect?

Commented [HJ24]: Again – or you had insufficient power to really test this.

Limitations

As in any population-based analysis of HIV care, ours had VL data only when persons sought care, which was at their discretion. Persons in this analysis were not necessarily tested at regular intervals. Persons may have achieved suppression sometime before it was measured in a VL test. It is not clear whether these circumstances would have increased or decreased the hazards ratios we found. However, all persons in the analysis had at least one VL test between 8 days post-diagnosis and censoring. Among them, persons diagnosed in 2009, for example, had a median of 13 VL tests (IQR: 7-17) and the median interval between tests was 140 days (<5 months; IQR: 106-264 days), while persons diagnosed in 2012 had a median of 8 tests (IQR: 6-10) and the median interval between tests was 85 days (<3 months; IQR: 67-98 days). These statistics indicate that the majority of New Yorkers recently diagnosed with HIV and interviewed by CSBS were engaged in care at intervals that were both consistent with federal guidelines and sufficiently frequent to produce estimates of suppression.

Persons in this analysis were interviewed by CSBS, numbered fewer than 100, and nearly universally achieved suppression by the end of follow-up. That these persons could be found in NYC and were sufficiently available for an interview suggests that they may differ from other recently diagnosed and reported New Yorkers, i.e., they may be more likely to still be living in NYC, be in care, and achieve suppression, although it is unclear whether this might affect the relationship between cohesion or poverty and suppression. Similarly, analyses of persons with HIV in NYC (who were not necessarily recently diagnosed, unlike our analysis population) found that many reported to surveillance appeared to no longer live in NYC, and when those were excluded, the rates of care were higher.[52] This analysis was conducted with a small population considering the numerous factors we sought to explore in multivariable analysis. With a larger population, we may have found additional individual characteristics – specifically, younger age and earlier year of diagnosis, whose AHRs indicated >30% reduced hazards of suppression but whose confidence intervals extended modestly above 1.0 – to be associated with delayed suppression, particularly given the findings of prior analyses among newly diagnosed New Yorkers that showed these characteristics to be important.[12, 53] Specifically, a larger population would have produced narrower confidence intervals that may have been entirely below 1.0 for the aforementioned factors. However, a larger analytic population may not have changed our findings that social cohesion and poverty were not associated with suppression. There is less evidence in the literature for these relationships, particularly as relates to social cohesion and HIV outcomes, and the AHRs for these characteristics in our analysis were closer to or equal to 1.0, so it seems unlikely that there was a substantial effect that we were simply underpowered to detect. Additionally, it may be that persons certainly in NYC (in this analysis, indicated by their findability for CSBS interview) have high rates of suppression and that differences by subgroups are relatively small, offering an alternative explanation of why only a few characteristics were significantly associated with suppression. A previous study of newly diagnosed persons who, according to surveillance records, appeared never to have entered HIV care found that three times as many of these persons self-reported that they were in fact in care as the number who agreed that they were out of care.[54] With near-universal care engagement among persons completing CSBS interviews, subgroup differences in suppression may indeed be minor, supporting our findings that few factors were associated with suppression.

Commented [HJ25]: Again this makes it sound like these are your exposures of interest – needs to be reflected in the methods section

Commented [HJ26]: I would state this in another way. "For example, in a previous analysis of all of the HIV cases in NYC, we found age and year of diagnosis also to be associated…"

Commented [HJ27]: Hmm – ok but could it also be how you coded them – you dichotomized them both to low vs. high – how many of them were close to the middle of this break so not that different from each other? For social cohesion – did you try just using a single question that had a scale of 1-4? How well were the questions correclated with one another – if the majority responded as 2, 3 or 4 to all of the questions (so their score was 6, 9 or 12) then perhaps just using a single question with a score from 1-4 would be more meaningful? Or collapse the 1 and 2 together if there were so few people who said 1, to have 3 groups?

There are several steps between diagnosis and suppression in the continuum of care for HIV-positive persons.[10, 55] By design, this analysis did not elucidate the exact step(s) at which the factors measured affect suppression. This means that the associations that we found exist for the overall process from diagnosis to suppression but not necessarily for individual steps between them. For example, ART eligibility may not influence time from diagnosis to linkage of care but rather only time from linkage to suppression.

Strengths

This is the first analysis to investigate the influence of perceived neighborhood social cohesion on HIV outcomes, and among the first US analyses to use surveillance data to investigate the role of neighborhood factors on HIV outcomes. [24-27, 56, 57] The data were drawn from population surveillance in the largest HIV epidemic in the US, in a diverse US city, and included only persons confirmed (by locating them at an NYC address) to still be in the jurisdiction. The analysis combined data from multiple sources to assess the potential influence on viral suppression of factors beyond the individual. Mandatory electronic reporting of laboratory tests in NYC provided information about all measured VLs for all HIV-positive persons receiving care in NYC, as opposed to in a clinical trials environment, where findings can differ from those in a population setting.

Commented [HJ28]: As I think about it more, this really seems to be your variable of interest (more so than neighborhood poverty – which you could do with all fo the registry data (I think) rather than with this very small subsample – perhaps it makes sense to frame this paper slightly differently to explore whether perceptions of neighborhood social cohesion impact HIV VL suppression after adjusting for individual level characteristics? If you want to know about neighborhood poverty, I would think you should use the larger sample size – unless you want to consider this another item to adjust for when exploring the impact of social cohesion

Conclusions

New Yorkers recently diagnosed with HIV, confirmed to be in NYC, and available for interview have almost universally achieved viral suppression. Just as black and Hispanic race and ethnicity and ineligibility for ART were associated with non-achievement of suppression, non-black, non-Hispanic race/ethnicity and ART eligibility seem to have helped persons newly diagnosed with HIV to achieve viral suppression faster, and thus, improve their health and preventing ongoing HIV transmission. Individuals with characteristics associated with slower achievement of suppression may need more assistance after diagnosis with linkage to and retention in care or ART prescribing and adherence. For example, black and Hispanic persons need better care that permits them to receive ART and become suppressed at comparable rates as whites;[12, 14, 17-19, 58] rectifying this disparity may require more equitable prescribing behavior and/or better adherence support.[59] This disparity was not related to estimated poverty status nor neighborhood poverty. Since 2010, New York State law has required all providers to

link positive patients to care, and the United States Department of Health and Human Services now encourages antiretroviral therapy for all diagnosed persons, regardless of CD4 count, which should further the improvement in suppression rates. Future studies should explore the extent to which persons who can be located for a CSBS interview are representative of persons with HIV in NYC.

Nice paper in general. I do think you could strengthen the overall narration to be a bit more focused as, it seems like you are most interesting in answering the question – does neighborhood social cohesion matter for HIV VL suppression. I think it would be easier for the reader to follow if everything is ultimately about the social cohesion story. What was your power to detect a difference for this variable? I think, if this really is your main variable/exposure of interest, you may want to explore coding it in different ways to see If that has an effect on the results.

I am grateful to my dissertation committee: Drs. Luisa Borrell, Heidi Jones, Andrew Maroko, and Lucia Torian. For her expertise and support, from the time that I applied to the DPH program, I thank my adviser and sponsor, Dr. Borrell (Lehman College, CUNY). I appreciate her epidemiology acumen, patience and responsiveness. She provided feedback generously and quickly and went the extra mile on numerous occasions to help me. I am lucky to have had her as my advocate. For their high standards and suggestions for improving my dissertation, I am grateful to Heidi (Hunter College, CUNY), Andrew (Lehman), and NAME REDACTED Their input has made my dissertation more rigorous and complete. Heidi suggested additional perspectives and analyses that strengthened my analyses and writing. Andrew ensured that geographic analysis methods were applied and interpreted properly. NAME REDACTED provided expert input on population-based analyses of care outcomes among New Yorkers with HIV, and extensive edits to help the dissertation read smoothly. Although they did not go easy on me, all of my committee members were easy to work with, and I do not take for granted their ability to strike that balance. I was lucky to have this committee of accomplished and dedicated public health professionals.

For their support for me using data from DOHMH, my place of work, for my dissertation, I am grateful to NAMES REDACTED. I also appreciate the guidance of staff of the DOHMH Employee Law Unit and the DOHMH and Lehman College Institutional Review Boards on appropriate use of city resources while a city employee as well as a student. I appreciate the support of my supervisor at the time that I was finishing the dissertation, NAME REDACTED who both saw my potential as someone who had almost completed the doctorate, and encouraged me to complete my degree requirements quickly. I also thank NAME REDACTED, my supervisor for the majority of my time as a DPH student, for her years of mentorship and advocacy for me. I am grateful for her high standards for, and guidance on, all aspects of the practice of epidemiology.

For their regular management of HIV-related surveillance databases in NYC, I thank NAMES REDACTED. I also thank the staff of the HIV Epidemiology and Field Services Program and providers

and laboratories that report HIV data to DOHMH. This dissertation benefitted from the completeness, accuracy, and timeliness of population-based HIV surveillance data in NYC. Thank you to NAMES REDACTED for sharing the SAS code and exclusion criteria that you had developed in your work examining viral suppression among newly diagnosed New Yorkers.

I am grateful to Dr. Denis Nash (CUNY School of Public Health) for his input on my dissertation proposal, including reflection on definitions of HIV-related care outcomes. I thank Denis too for hiring me into the office of DOHMH that would ultimately provide me with over a decade of meaningful work as well as most of the data for my dissertation.

For their geocoding of data on the residences of New Yorkers with HIV, I am grateful to NAMES REDACTED. I am also grateful to NAMES REDACTED for geocoding the addresses of facilities diagnosing and providing care to New Yorkers with HIV. Because of the tenacity of both groups in the course of their regular job duties, it was possible to identify places of residence by Census tract, the gold standard for identification of public health disparities, and to conduct network analysis (i.e., calculate the distance between places of residence and health care facilities) based on XY coordinates. For their help with the network analysis itself, I would like to thank NAME REDACTED for providing the network dataset and help with the Network Analyst application; and NAME REDACTED for providing help with Network Analyst, including remotely walking me through the actual routing.

For implementing Case Surveillance-Based Sampling (CSBS) in NYC in the course of her work, supporting my request to add to CSBS local questions on perceived neighborhood social cohesion, and permitting me to work with CSBS data, I thank NAME REDACTED. I also NAMES REDACTED, who conducted study interviews or managed the data.

For setting examples and providing support as fellow students, I am grateful to my DPH classmates from the Epidemiology track, from the 2009 DPH cohort, or from DOHMH. Specifically, thank you to NAMES REDACTED. I am also grateful to my friend NAME REDACTED for shining a light on the doctoral student experience and providing encouragement throughout the process.

I acknowledge the New Yorkers with HIV who indirectly provided data for these analyses in the course of population-based surveillance. I hope that our findings will be used to promote additional health improvements for this population, on top of the remarkable advances that have occurred over the last three decades of the epidemic.

On a light note, I thank my fellow commuters on the Long Island Rail Road for making room for me and my laptop in all of those middle seats during the evening commute so that I could write this.

In seriousness, I am indebted to my family. For the value they placed on education, and the examples they set as professionals devoted to bettering the world, I am grateful to my parents, Drs. . Few doctoral students have the benefit of two loving, inspirational parents who are professional educators with doctorates themselves. This made the degree that much more achievable for me. I am also grateful to my brother, , for demonstrating that educational excellence on any timeline is worth striving for and best attained with humility. These examples are inspiring to a daughter, sister, and doctoral student.

Finally, I am grateful to my husband NAME REDACTED and our daughter NAME REDACTED. They provided the greatest support and the worthiest distractions (which is an imperfect way to describe “life”) during this long journey. I thank NAME REDACTED for his patience and perspective, and him and NAME REDACTED for their good humor and love. I think both of them respect me for my educational pursuits, but that has never been the basis of my worth to them. I appreciate their devotion.

Autobiographical Statement 118

Chapter 1. Introduction

HIV and viral suppression in the US and NYC

New York City (NYC) is home to more than 7% of all persons newly diagnosed with HIV in the United States (US) each year.[1, 2] It is recommended that persons newly diagnosed with HIV have their viral load (VL) measured as soon as they begin HIV-related medical care and then at least every six months.[3] Acute HIV infection typically is accompanied by very high VL (e.g., >100,000 copies of HIV ribonucleic acid, RNA, per milliliter, mL, of blood) which eventually declines to a lower set point that varies by individual. Reduction to low or undetectable levels (e.g., ≤400 copies/mL) is called viral suppression and is typically achieved by being treated with antiretroviral therapy (ART).[4] Because of improvements in ART since the mid-1990s, and recommendations that ART should be initiated before persons with HIV become immunocompromised, HIV has been transformed from an almost inevitably fatal disease to a chronic, manageable condition. In addition, because of these changes, viral suppression has become more common than virologic failure (i.e., when VL becomes detectable or reaches a high level), among persons living with HIV or acquired immunodeficiency syndrome (AIDS; PLWHA). Provided that the virus is sensitive to the multi-drug regimen chosen and the person is adherent, ART suppresses virus quickly (within 24 weeks) and durably.[5, 6] Achievement and maintenance of viral suppression, and avoidance of virologic failure, slows progression of HIV disease,[7] and reduces the likelihood of onward sexual transmission.[8] The 2015 goal of the US National HIV/AIDS Strategy is a 20% increase in the proportion of persons virally suppressed within three of the populations most affected by HIV (blacks, Hispanics, and gay and bisexual men).[9] As few as 20% of PLWHA were thought to be suppressed in the US in the early 2000s, while today most estimates exceed 50%;[10-14] in NYC, it was 59% in 2010.[14] During 2006-2009, suppression within 12 months of HIV diagnosis in NYC increased from 36% to 45%, and maintenance of suppression for 12 months (and avoidance of failure) increased over the same period from 79% to 86%.[15]

Summary of the literature and current gaps in knowledge

Epidemiologic literature has explored factors related to viral suppression and virologic failure among persons with HIV. However, studies have rarely examined VL over time or in terms of factors other than individual demographics and clinical characteristics.[15, 16] With respect to time measurement, most published population-level VL statistics, including those with the recent focus on the HIV care continuum, refer only to the most recent VL.[10, 13] A single VL may indicate neither maintenance of suppression (also referred to as sustained suppression) nor virologic failure.[16] The few population-based studies following persons' viral loads over time have found that substantial proportions of those achieving suppression do not maintain it.[15, 17-19] For example, among newly diagnosed New Yorkers achieving suppression, 18% experienced virologic failure within 12 months.[15] I measured time from HIV diagnosis to first viral suppression and time from first suppression to virologic failure, with a follow-up time of up to seven years.

More rapid achievement of suppression, longer maintenance of suppression, and lower failure rates have been associated with individual-level demographic characteristics including older age,[13, 15, 20] male sex,[15, 21-23] non-black race,[13, 15, 24-28] baseline clinical status indicators such as CD4 count and VL,[15, 29, 30], and more recent calendar year of diagnosis.[15] For example, in the CDC's Medical Monitoring Project, among persons with HIV on ART, 79% of males achieved suppression as compared with 71% of females.[13] An analysis among newly diagnosed residents of Seattle and surrounding King County found that blacks had 15% decreased odds of suppression compared with whites, while Hispanics had similar odds as whites.[25]

Studies of achievement and maintenance of suppression may further benefit from the addition of variables describing characteristics of health care facilities where people are diagnosed and receive care as well as neighborhoods where people live. For example, facility characteristics, such as type of clinical setting, accessibility including travel distance, support services offered, and physician experience have been shown to influence intermediary health outcomes among persons with HIV, including receipt of and adherence to ART, both necessary steps for maintenance of viral suppression.[31-35] Specifically, a large sample of US hospitals found lower mortality for patients in dedicated AIDS units relative to those in

hospitals without these units.[36] Studies in developing countries have found that clinic distance from patient residence influences linkage to care, an important precursor to viral suppression.[37] I am not aware of studies examining the effect of facility distance on HIV-related outcomes entirely within a large city in an industrialized nation.

Neighborhood factors such as lower area-level socioeconomic status have been associated with higher rates of diagnosis of HIV or AIDS, delayed care and treatment, and increased mortality.[31, 33, 38-43] Additionally, lower perceived neighborhood social cohesion has been associated with lower primary care use among older urban adults[44] as well as lower condom use and higher STI rates among urban adolescents and young adults[45, 46]. The latter factors (condom use and STI rates) have the potential to influence the time from HIV diagnosis to viral suppression. More broadly, public health researchers have characterized social and structural factors, such as individual- and neighborhood-level poverty, as fundamental drivers of health disparities and encouraged the inclusion of such broader factors in epidemiologic analyses.[47-50] For example, the Alameda County Study was one of the first epidemiologic studies to identify an effect of area-level factors on individual health, and it did so in a general population, not a population of persons with HIV: individual mortality risk was found to be higher among persons living in high-poverty areas than low-poverty areas, even after controlling for factors including individual income.[51] However, few studies on virologic suppression or failure have examined facility or neighborhood characteristics.[31-34] I assessed the impact of facility and neighborhood characteristics on the achievement and maintenance of viral suppression while controlling for individual characteristics.

Individual and facility characteristics associated with achievement and maintenance of viral suppression can now be measured by many HIV surveillance registries[15, 25, 52] and will become increasingly important as more persons with HIV receive ART and achieve suppression. Area-level data aggregated from individual responses to national data sources, such as the US Census and the American Community Survey (ACS), can supplement surveillance data with neighborhood-level variables, and can be matched to individual-level surveillance data by patient residence. I linked data from the US Census and ACS with data from the HIV surveillance registry to conduct these analyses.

Overview of the dissertation

Overall goals

I investigated the effect of individual, health care facility, and neighborhood characteristics on the achievement and maintenance of HIV viral suppression, among New York City residents aged 13 years and older who were diagnosed with HIV between 2006 and 2012. The results may be used to improve public health by identifying groups of persons with lower rates of achievement or maintenance of viral suppression who might benefit from interventions to improve ART initiation and adherence.

Specific aims

The following specific aims were addressed:

AIM 1: Examine the independent effects of individual-, neighborhood- and health care facility-level characteristics on HIV viral suppression, among adults and adolescents in New York City who were newly diagnosed with HIV between 2006 and 2010.

AIM 2: Examine the independent effects of individual-, neighborhood- and health care facility-level characteristics on HIV virologic failure, among adults and adolescents in New York City who were newly diagnosed with HIV between 2006 and 2010.

AIM 3 (exploratory aim): Examine the independent effect of perceived neighborhood social cohesion on HIV viral suppression, among adults in New York City who were newly diagnosed with HIV between 2006 and 2012.

Organization of the dissertation

Following this introduction, the dissertation contains four additional chapters. Chapter 2 assesses the individual, facility, and neighborhood factors associated with achievement of viral suppression after diagnosis among New Yorkers newly diagnosed with HIV in 2006-2010 (Aim 1). Chapter 3 begins with the subset of persons from the previous aim who achieved viral suppression and assesses the individual, facility, and neighborhood factors associated with maintenance of viral suppression (Aim 2). Chapter 4 assesses individual and neighborhood factors, including perceived neighborhood social cohesion,

associated with achievement of viral suppression after diagnosis, among a sample of New Yorkers newly diagnosed with HIV in 2006-2012 (Aim 3). Chapter 5 summarizes findings from aims 1-3 and discusses limitations and strengths of the analyses. Finally, I conclude with policy implications and directions for future research.

Data sources

In this dissertation, I used individual-level data from the NYC HIV surveillance registry and Case Surveillance-Based Sampling,[53] facility-level data from the registry, and Census-tract- and ZIP-code-level data from the 2010 US Census[54] and the 2011 American Community Survey.[55] The registry includes all persons diagnosed with HIV and reported in NYC since 2000 and all persons with AIDS since 1981. It gathers information by medical record review, provider report at diagnosis, and HIV-related laboratory tests, which are electronically reported to surveillance for all newly confirmed and existing cases. With respect to first HIV/AIDS diagnosis date, the concordance of surveillance data with medical records is high (84% of NYC AIDS patients identified via medical record had been reported to the surveillance registry) and with self-report somewhat high (56% of US HIV surveillance-self-report pairs had the same year of diagnosis, and 30% of self-reported dates were an earlier year).[56-58] Surveillance data are also timely, with reportable events typically confirmed and appearing in the registry within several months.[57]

The registry includes individual-level demographic and clinical information collected at the time of first report of HIV diagnosis (Aims 1 and 3) or first VL test indicating suppression (Aim 2), address of residence at diagnosis, and HIV-related laboratory test results from 2006-2012 for all New Yorkers newly diagnosed with HIV. Laboratory reports contain the test type, specimen collection date, result, and submitting provider or facility. Health care facility data from 2006-2012 were obtained from the registry and linked to cases according to the facility diagnosing the patient (Aims 1 and 3) or that conducted the first VL test indicating suppression for each case (Aim 2). Finally, neighborhood data were acquired from the 2010 US Census and the 2011 American Community Survey 5-year estimates. Neighborhood data were geocoded and linked to cases through patient residence at the Census tract level (Aims 1 and 2) or ZIP code level (Aim 3). Case Surveillance-Based Sampling was used for Aim 3, including the main questionnaire of the project and three local, scaled questions about whether people in the patient's

neighborhood of residence were trustworthy, close-knit, or willing to help neighbors. Answers to these three questions were combined to create a composite measure of perceived neighborhood social cohesion.[45]

Outcomes

The outcomes of interest were first viral suppression after diagnosis (Aims 1 and 3) and failure after first suppression (Aim 2). The cut-off for suppression in all three aims was 400 copies/mL because this was the highest (i.e., least-sensitive) lower detectable limit of all VL assays used during the study period.[59] In Aim 2, virologic failure was defined as having a VL ≥1,000 copies/mL or not having any VL test for 12 consecutive months. The 1,000-copy cutoff permitted a temporary blip that would not necessarily signal virologic failure since VL changes easily,[60] and risk of HIV transmission from a person with a VL under 1,000 copies/mL is almost nonexistent.[8, 61] Requiring VL tests every 12 months in order to be considered as maintaining suppression ensured at least minimal engagement in care and provided an endpoint for persons who dropped out of care, since care was required to detect any VL and it was unreasonable to assume that persons who dropped out of care in NYC would remain suppressed. The follow-up period for Aims 1 and 2 ended on 12/31/2012 and for Aim 3 on 6/30/2014.

Study population

Our analysis population was drawn from NYC residents who were newly diagnosed with HIV between 2006 and 2010 (Aims 1 and 2) or between 2006 and 2012 (Aim 3) and were at least 13 or 18 years of age at diagnosis (Aims 1 and 3, respectively) or at least 13 at suppression (Aim 2). Aim 2 was limited to the subset of these persons who achieved viral suppression (≤400 copies/mL) ≥31 days following diagnosis and by 12/31/2012. Aim 3 assessed viral suppression for a much smaller population (hence its exploratory nature), because it drew from a survey of persons sampled from new diagnoses through 2012. These persons' addresses were not geocoded to XY coordinates, so neighborhood-level variables were constructed at the level of ZIP code.

Persons were excluded from the analysis population if their death date appeared to precede their first diagnosis (Aims 1 and 3) or suppression date (Aim 2), their date of HIV diagnosis or viral suppression was potentially misclassified, information about address or neighborhood of residence and facility of diagnosis or suppression was missing, or their address data indicated that they were homeless or

institutionalized. These exclusions yielded an analytic sample of 12,547 persons in Aim 1, 8,927 persons in Aim 2, and 92 persons in Aim 3 (see Appendix 1 and Appendix 2).

Statistical analysis

Descriptive statistics were calculated for selected characteristics at the individual, health care facility, and neighborhood levels and presented for the overall population and according to viral suppression status (Aims 1 and 3) or virologic failure status (Aim 2) within 12 months of diagnosis. The association between each variable and virologic suppression or failure within 12 months was estimated using Chi-square statistics; differences in median days to suppression or failure were assessed using the Mann-Whitney U test.

Kaplan-Meier curves showing the number of days from diagnosis to suppression (Aims 1 and 3) or suppression to failure (Aim 2) were generated for key individual, health care facility, and neighborhood characteristics; log-rank tests were used to assess differences between groups.

Cox proportional hazards regressions estimated the association of individual, facility, and neighborhood-level factors with suppression (Aims 1 and 3) or failure (Aim 2) in crude and adjusted models. When the analytic sample was sufficiently large (Aims 1 and 2), these regressions were multilevel. Specifically, robust sandwich estimation of the standard errors was used to account for correlations of individual outcomes clustered within either facility or neighborhood (Census tract).[62, 63] After estimating unadjusted rates for suppression (Aims 1 and 3) or failure (Aim 2) for each individual, facility, and neighborhood characteristic, models were fitted to estimate the hazards of virologic suppression or failure for each characteristic, after adjustment for other characteristics.

Previous epidemiologic studies of viral suppression have often used survival analysis as their methodology.[15, 29, 64, 65] This time-to-event technique is useful for measuring the amount of time between HIV diagnosis and first achievement of viral suppression. It can also be used to measure the amount of time that suppression is maintained after it is achieved, i.e., until virologic failure. Survival analysis also permits persons to be in the analysis for only part of the study period, even if they enter it after the start date (e.g., they are newly diagnosed with HIV during the follow-up period) or leave before the end date (e.g., they are lost to follow-up before they have the outcome of interest). The multilevel models in Aims 1 and 2 permitted examination of the influence of social and structural (i.e., neighborhood

and facility) factors and of potential mechanisms by which individual factors such as race/ethnicity might be associated with suppression.

Applications of findings

The findings of these analyses may be valuable to agencies planning testing programs, medical care for individuals with HIV, and "prevention with positives" programs. They may also help strengthen existing programs, such as the NYC care coordination program and housing services, which appear to be working,[66, 67] or help explain why other programs may not be working. Findings about neighborhood characteristics associated with shorter time to suppression and longer maintenance of suppression could identify geographic groups of persons in need of additional services. They might also influence future assessments of areas that could benefit from subsidized and/or supportive housing for persons with HIV. Health care facility characteristics associated with shorter time to suppression and longer maintenance of suppression could be examined for their "best practices" and these practices considered either for scale-up across facilities or in recommendations of which types of facilities have the potential to provide the best care. Further analyses could assess how populations with long-term detectable VLs could be offered greater support via facility- and neighborhood-level changes, or how HIV care and services generally could be structured to maximize (a) the linkage of persons with HIV to facilities that have successfully helped patients like them achieve and maintain suppression and (b) the housing of persons with HIV in neighborhoods or other communities with suppression-supporting characteristics.

Ethical considerations

Ethical approval for these analyses was provided by the Institutional Review Boards of Lehman College of the City University of New York and of the New York City Department of Health and Mental Hygiene. Maintenance of confidentiality and privacy of person-level information was a top priority throughout the research process. Among other protections, all person-level data were maintained on computer servers of the New York City Department of Health and Mental Hygiene and analyzed in the Department's HIV Epidemiology and Field Services Program, which conducts HIV surveillance and has numerous facility, technical, electronic, and procedural safeguards to promote security and minimize opportunities for breaches. The doctoral student underwent confidentiality training at the Department,

passed the Basic Course for social and behavioral research with human subjects via the Collaborative Institutional Training Initiative (CITI), and had over 10 years of professional experience working with data in the HIV Epidemiology and Field Services Program, which conducts HIV surveillance.

Chapter 2. Multilevel analysis of individual, health care facility, and neighborhood characteristics associated with achievement of HIV viral suppression among persons newly diagnosed with HIV in New York City

Introduction

New York City (NYC) is home to more than 7% of all persons newly diagnosed with HIV in the United States (US) each year.[1, 2]. It is recommended that persons newly diagnosed with HIV have their viral load (VL) measured as soon as they begin HIV-related medical care and then at least every six months.[3] HIV infection typically is followed by a very high VL (e.g., >100,000 copies of HIV RNA per milliliter of blood) which eventually declines to lower levels that vary by individual. Further reduction of HIV VL to low or undetectable levels (e.g., ≤400 copies/mL) is referred to as viral suppression. Although a small percentage of persons (i.e., “elite controllers") is able to achieve suppression without treatment, most persons achieve suppression by being treated with antiretroviral therapy (ART).[4] Provided that the virus is sensitive to the multi-drug regimen chosen and the person is adherent, ART helps a person achieve suppression quickly (within 24 weeks) and durably.[5, 6]

Viral suppression not only slows progression of HIV disease [7] but also reduces the likelihood of onward sexual transmission.[8] As few as 20% of PLWHA were thought to be suppressed in the US in the early 2000s, while today most estimates exceed 50%;[10-14] in NYC, it was 59% in 2010.[14] In 2010, the US National HIV/AIDS Strategy set as a goal a 20% increase by 2015 in the proportion of persons in populations most affected by HIV (blacks, Hispanics, and gay and bisexual men) who are virally suppressed.[9]

Although retention in care and ART are the main drivers of viral suppression, more rapid achievement of suppression has also been associated with individual-level demographic characteristics (e.g., older age,[13, 15, 20] male sex,[21-23] and non-black racial/ethnic category [13, 24-28]), and baseline clinical status indicators (e.g, CD4 count and VL[15, 29, 30]).

Studies focusing on individual-level factors affecting viral suppression may benefit from the addition of variables describing characteristics of health care facilities in which people are diagnosed, as these characteristics have been shown to influence intermediary health outcomes among persons with HIV.[31-33] For example, facility-level characteristics have been associated with linkage to care after

diagnosis,[35] receipt of ART,[33, 34] and adherence to treatment, all necessary steps toward viral suppression.[32] The type of clinical setting and accessibility of a medical facility including travel distance for patients, as well as the support it offers its patients, can affect adherence.[32] Few studies on viral suppression, however, have included these facility characteristics.[31-33]

Similarly, the relationship between neighborhood-level socioeconomic characteristics and viral suppression has rarely been studied. Lower socioeconomic status has been associated with higher rates of diagnosis of HIV or AIDS, delayed access to treatment, and mortality.[31, 33, 38-43] For example, in a US city, HIV-positive residents of higher-unemployment neighborhoods were less likely to be on ART.[43] Even in a province of Canada, a country with universal health care and free HIV treatment, after controlling for clinical characteristics, it was found that residents of lower-SES neighborhoods (as measured by median income) were less likely than residents of higher-SES neighborhoods to be prescribed the ART regimen that was the standard of care.[33] We therefore investigated the effect of individual, health care facility, and neighborhood characteristics on achievement of viral suppression, among NYC residents ≥13 years of age who were diagnosed with HIV between 2006 and 2010, before and after controlling for selected characteristics.

Methods

Data sources

This retrospective analysis used data from the NYC HIV surveillance registry, the 2010 US Census,[54] and the 2011 American Community Survey.[55] The registry includes all persons diagnosed and reported with HIV in NYC since 2000. It gathers information by medical record review, provider report at diagnosis, and HIV-related laboratory tests, which are electronically reported to surveillance for all existing cases receiving diagnosis and/or care in NYC.

Individual-level data acquired from the registry included demographic and clinical information collected at the time of first report, address of residence at diagnosis, and HIV-related laboratory test results from 2006-2012 for all New Yorkers diagnosed with HIV. Laboratory reports contain the test type, specimen collection date, result, and submitting provider or facility. Reports on existing cases are added to their surveillance registry record; reports not matching an existing case are sent out for field investigation to confirm the diagnosis and collect other registry data. Health care facility data from 2006-

2012 were obtained from the registry and linked to cases according to the facility diagnosing each case with HIV. All registry data were reported as of September 30, 2013. Finally, neighborhood data at the Census tract level were acquired from the 2010 US Census and the 2011 American Community Survey 5-year estimates. Neighborhood data were linked to cases through the Census tract of patient residence, which was geocoded from address of residence to the 2010 Census tract. The process of creating an analytic dataset with individual, facility, and neighborhood data is described in Appendix 3.

Population

NYC residents who were newly diagnosed with HIV between 2006 and 2010 and at least 13 years of age at diagnosis (N=17,825 persons) were excluded if their address could not be geocoded to Census tract (n=2,560), if their facility- or neighborhood-level characteristics were unknown (n=206), if their address of residence and of facility of diagnosis were equivalent, possibly indicating a homeless or institutionalized person (n=471), if they were diagnosed at a correctional facility (n=252), or if they did not survive at least 31 days following diagnosis (n=220). We further excluded 1,569 persons with neither a Western blot confirmatory test within 31 days of diagnosis nor a diagnosis of acute HIV infection (n=716); persons with a detectable (>50 copies/mL) viral load >31 days prior to diagnosis (n=1); and persons with a suppressed (<400 copies/mL) viral load <31 days following diagnosis, values that indicate either elite controllers or previous use of ART (n=852). These exclusions yielded an analytical sample of 12,547 persons (see Appendix 1).

Outcome

The outcome of interest was the first suppressed VL (≤400 copies of HIV RNA/mL plasma) after HIV diagnosis. The cut-off was 400 copies/mL because this was the highest lower detectable limit of all VL assays in use during the study period.[59] Persons were censored at death or the end of the follow-up period, whichever came earlier. Follow-up time was calculated as the number of days from the date of HIV diagnosis to suppression, death, or 12/31/2012, whichever came first.

Treatment guidelines evolved during the analysis period but recommended VL tests between 2-4 times per year after HIV diagnosis. However, some persons with HIV may have had infrequent or no VL tests after diagnosis, because they were never linked to HIV-related medical care, they sought care infrequently, or their physician did not test their VL at every care visit. Persons who were not known to be

dead and who had no suppressed VL (including persons with infrequent or no VL tests) were presumed not to be suppressed and contributed follow-up time as long as they were alive.

Covariates

Individual-level variables

Demographic characteristics (age, sex at birth, race/ethnicity, area of birth), HIV transmission risk (also referred to as transmission categories), diagnosis date, viral loads, CD4 counts, and address of residence at diagnosis were extracted from the NYC HIV surveillance registry. Age at HIV diagnosis was calculated from birth date and date of diagnosis and categorized as 13-19, 20-29, 30-39, 40-49, 50-59, and 60+.[2] Sex at birth was classified as male or female. Race was collected as white or Caucasian, black or African American, Asian or Pacific Islander, and Native American. Ethnicity was collected as Hispanic, non-Hispanic, or unknown. Race and ethnicity were combined into a single variable in which all persons of Hispanic ethnicity were classified as Hispanic, and non-Hispanics were classified as black, white, or other non-Hispanic race (which included Asians and Pacific Islanders, Native Americans, and multiracial persons).[15] Area of birth was collected as country of birth when available or region of birth and categorized as born in the US, US dependency (e.g., Puerto Rico), foreign country, or unknown place of birth.[68] HIV transmission risk category was based on the self-reported pre-diagnosis risk behaviors of the case (e.g., injection drug use, male-male sex) and the sex, HIV status (e.g., HIV-positive), and risk (e.g., injection drug use) of the pre-diagnosis heterosexual-sex partners that s/he reports (which could indicate high-risk heterosexual risk).[69] This information was combined into hierarchical, mutually exclusive categories for the case: injection drug use (IDU), men who have sex with men (MSM), heterosexual sex, and other or unknown (which included perinatal transmission).[15] To be classified as a heterosexual male or female, persons must have reported pre-diagnosis sex with a partner of the other sex who was HIV-infected, had injected drugs, or had received blood products. In addition, females only could be classified as heterosexual if they had probable heterosexual transmission noted in their medical record, reported sex with a male and no history of drug injection, or had any one of several behaviors associated with heterosexual transmission: history of prostitution, multiple sex partners, sexually transmitted disease, crack/cocaine use, or sex with a bisexual male.[2] For analytic purposes, the year of diagnosis was determined from the earlier of physician diagnosis date or positive Western blot test result (2006, 2007, 2008, 2009, 2010). CD4 count (if any) at diagnosis (i.e., within 3 months of diagnosis) and

year of diagnosis vis-à-vis treatment guidelines were used to estimate treatment eligibility and as a proxy for receipt of ART, on the presumption that the majority of persons reaching the federal treatment threshold would be offered and receiving ART. Treatment-eligible persons included those diagnosed in 2006-2007 and with CD4<200, diagnosed in 2008-2009 and with CD4<350, or diagnosed in 2010 and with CD4<500, reflecting changing treatment guidelines that increased the CD4 count at which ART initiation was recommended.[70-72] All other persons, including those with no reported CD4 counts, were not known to be eligible and were classified as not eligible.

Health care facility-level variables

Facility-level characteristics include annual HIV patient volume, facility type, and patient-facility distance. HIV patient volume was collected as number of new HIV diagnoses made annually, based on diagnoses attributed by surveillance to that facility in the year of the patient's diagnosis, and categorized as <10, 10-24, 25-49, 50-74, and ≥75 diagnoses per year.[33, 73] Facility type was categorized as inpatient/hospital, private provider, other outpatient facility, screening/diagnosis/referral facility, and other or unknown (<10 persons had a known facility but unknown type), as potential indicators of the availability of colocated care (at the first three facility types) [35] and ancillary services (at the first and third types) [32]. Patient-facility distance was calculated as the distance in miles along NYC streets from patient residence to the facility of diagnosis (based on the XY coordinates of each) using Network Analyst in ArcMap 10.0 (ESRI, Redmonds, CA) (see Appendix 4). This distance was categorized as <1 mile, 1-<5 miles, 5-<10 miles, and ≥10 miles.

Neighborhood-level variables

Analyses included two Census tract-level SES measures from 2011 American Community Survey (ACS) 5-year estimates, which is the recommended source for such statistics because the 2010 decennial census did not collect them.[74] These measures, which previously have been associated with HIV or sexually transmitted infections or HIV outcomes, were percent of residents with incomes under federal poverty threshold,[31, 33, 39, 40, 47, 75] and percent unemployed among residents 16+,[31, 39, 41, 75] Census 2010 provided data on percent of non-Hispanic black residents, as it is the recommended data source for population race/ethnicity statistics. [74] The values for percent unemployed and percent black were divided by 10 and entered into a proportional hazards regression as continuous variables; measures of association would therefore be for 10-percentage-point differences. Poverty was

categorized as 0 to <10% (low-poverty), 10 to <20% (medium-poverty), 20 to <30% (high-poverty), and 30 to 100% (very-high-poverty), based on recommendations of the NYC health department.[76] This particular set of three neighborhood-level variables (poverty, unemployment, and percent black) has been used previously.[43]

Statistical analysis

Descriptive statistics were calculated for selected characteristics at the individual, health care facility, and neighborhood levels and presented for the overall population and according to suppression status within 12 months (365 days) of diagnosis. The association between each variable and achievement of suppression within 12 months was measured using Chi-square tests. The Mann-Whitney U test was used to ascertain differences in median days to suppression by the end of the follow-up period.

Kaplan-Meier curves showing the number of days from diagnosis to suppression were generated by key individual and health care facility characteristics, and log-rank tests were used to indicate differences between groups.

We used Cox proportional hazards regressions to estimate the association of individual, facility, and neighborhood-level factors with suppression in crude and adjusted models. Robust sandwich estimation of the standard errors was used to account for correlations of individual outcomes clustered within either facility of diagnosis or neighborhood (Census tract).[62, 63] Unadjusted models were fitted to estimate the unadjusted hazards of viral suppression for each individual, facility, and neighborhood characteristic. In addition, several models were fitted. First, hazards of viral suppression for each individual characteristic were estimated after adjustment for all other individual characteristics. Second, models were fitted to estimate the hazards for each facility and each neighborhood characteristic, after controlling for individual characteristics. Finally, two models were fitted to estimate the adjusted hazards for 1) all individual and facility characteristics and 2) all individual and neighborhood characteristics.

All analyses were conducted using SAS 9.2 (SAS Institute, Cary, NC). Ethical approval for these analyses was provided by the Institutional Review Boards of Lehman College of the City University of New York and of the NYC Department of Health and Mental Hygiene.

Results

Descriptive statistics

Of 12,547 New Yorkers newly diagnosed with HIV in 2006–2010, approximately three-quarters were 20-49 years old (78.7%), male (74.2%), and black or Hispanic (81.5%; Table 2.1). In addition, approximately half were US-born (53.5%) and MSM (44.5%), and about one-third were eligible to receive treatment based on CD4 and diagnosis year (30.6%). Forty-four percent of the population achieved suppression within 12 months of diagnosis. Those who did not suppress within 12 months were more likely to be younger, black, US-born, MSM or IDU, diagnosed in earlier years, and not eligible for treatment.

Almost three-quarters of the population (72.8%) achieved viral suppression by 12/31/2012 (not shown), in a median of 245 days (Table 2.1). Suppression happened least quickly among persons who were younger, diagnosed in earlier years, and not known to be eligible for treatment; differences were most prominent by treatment eligibility (127 days among eligible vs. 415 days among not eligible), differences also demonstrated in Kaplan-Meier survival curves (p<0.0001; Figure 2.1a).

Approximately half of the population was diagnosed in facilities that diagnosed 10-74 persons (45.0%), were hospitals (42.7%), and were 1 to <5 miles from their home (51.0%; Table 2.2); and lived in neighborhoods where ≥20% of the population was below the poverty threshold (i.e., high or very high poverty; 58.0%). Neighborhoods where people lived had a mean unemployment rate of 10.8%, and black persons comprised a mean of 34.3% of the population.

When compared to persons achieving suppression within 12 months of diagnosis, those who did not achieve it were more likely to be diagnosed at facilities that diagnosed fewer persons with HIV, were screening or outpatient facilities, and were ≥10 miles from the patient's residence (Table 2.2); differences in suppression by the first two characteristics were also visible in Kaplan-Meier survival curves (Figures 2.1b and 2.1c). Suppression happened least quickly among persons diagnosed at non-hospital facilities and facilities farther from the patient's residence.

Modelling individual characteristics

Table 2.3 presents the unadjusted and adjusted HRs for individual characteristics on HIV viral suppression among persons newly diagnosed with HIV in NYC. The unadjusted HRs show that persons who were younger, male, black, US-born or MSM were at least 7% less likely to achieve viral suppression

(range 7% to 43%). The same decrement applied to those diagnosed before 2010 and those who were not treatment-eligible.

After adjusting for individual characteristics, the likelihood of viral suppression was 16-29% lower for persons 13-49 years old relative to those 60 and older (e.g., 20-29 years old, 24%[95%CI=0.67-0.86]) and 10% (95%CI=0.83-0.97) lower among men than women. Blacks and Hispanics were 19% (95%CI=0.76-0.86) and 12% (95%CI=0.82-0.94) less likely to suppress than their white counterparts. US-born persons were 8% (95%CI=0.87-0.97) less likely to suppression than foreign-born, and persons diagnosed in 2006 and 2008 were at least 11% (e.g., 2006, 11%[95%CI=0.83-0.96]) less likely to suppress than persons diagnosed in 2010. Compared with heterosexuals, MSM went from being less likely (in crude models) to as or more likely (in models adjusting for other individual characteristics) to suppress (AHR[95%CI]=1.08[1.00-1.17]). Finally, persons not eligible for treatment were 65% less likely than treatment-eligible persons to suppress, presumably because treatment-eligible persons were more likely to have been prescribed ART, almost the exclusive means of lowering viral load. These findings remained nearly identical when adjusting for either facility or neighborhood characteristics (AHRs 2 and 3 in Table 2.3).

Modelling facility and neighborhood characteristics

Table 2.4 presents the unadjusted and adjusted HRs for facility and neighborhood characteristics on HIV viral suppression among persons newly diagnosed with HIV in NYC. The unadjusted HRs show that persons diagnosed at facilities diagnosing <10 patients per year or that were a type other than a hospital were at least 10% less likely to achieve viral suppression (range 10% to 38%; e.g., outpatient facilities, 25% [95%CI=0.71-0.79]). At facilities 1 to <5 miles from the patient vs. <1 mile, 8% more likely (95%CI=1.02-1.14). Although marginally significant, each 10% increase in the proportion of neighborhood residents that was unemployed or black was associated with, respectively, a 5% (95%CI=0.92-0.99) and 1% (95%CI=0.98-0.99) lower likelihood of suppression.

After adjusting for individual characteristics alone, and then individual characteristics as well as either facility or neighborhood characteristics, facility-related findings remained similar as in the bivariate models, with the exception of persons diagnosed at private physicians becoming more likely to achieve suppression (when controlling for both individual and facility characteristics, AHR[95%CI]=1.08[0.95-1.22]). The model with all individual- and facility-level variables had the best fit (-2LL: 158,585; p<0.0001

vs. the model with all individual-level variables only; see Appendix 5). Neighborhood characteristics were no longer associated with suppression in models adjusted for individual characteristics.

Discussion

Controlling for individual and facility characteristics, persons who were younger, male, non-white, US-born, non-MSM, diagnosed in earlier years, and not eligible for treatment took longer to achieve HIV viral suppression after diagnosis. Persons diagnosed at facilities that diagnosed relatively few patients or that were screening, diagnosis, and referral sites also took longer to suppress. Neighborhood-level characteristics did not influence the time from diagnosis to viral suppression.

Our findings about individual and facility characteristics were consistent with the literature. Individual-level factors associated with suppression were similar to a previous study using NYC HIV surveillance data.[15] After adjustment for other individual characteristics, MSM went from having slower suppression than heterosexuals to as quickly or quicker. One possible explanation is that newly diagnosed MSM were younger, healthier, and less likely to be eligible for ART than heterosexuals, but compared with heterosexuals, MSM had equivalent or better treatment access generally and/or adherence once on ART. However, our findings provided unique information about teenagers, who have been included in few prior analyses of viral suppression. Our analysis found teenagers to have, relative to persons ≥60 years old, similarly reduced rates of suppression as persons in their 20s. Teenagers are known to face challenges linking to care after diagnosis, being retained in care, and adhering to ART to achieve suppression;[77, 78] these age-related disparities are not entirely attributable to teenagers being in an earlier stage of disease than older persons. Persons diagnosed at facilities that diagnosed fewer patients or that only screened, diagnosed, and referred patients had lower rates of suppression than persons diagnosed elsewhere. It is possible that these facilities were less likely to provide on-site HIV-related medical care or services for retention, adherence, and case management, which have been shown to facilitate linkage after diagnosis[35] and retention in care;[79, 80] or because their providers are less likely to adhere to HIV-related care recommendations.[81]

Findings about neighborhood characteristics were not consistent with the scant literature on their relationship with HIV outcomes. While neighborhood-level socioeconomic factors have been associated with HIV diagnosis rates in NYC and elsewhere, and some care-related outcomes,[31, 33, 38-42] in our

analysis, neighborhood characteristics were not associated with time to suppression once diagnosed. Several possible explanations include different outcomes (e.g., time from ART initiation to suppression vs. time from diagnosis to suppression) and different settings (e.g., Canada vs. US, or other US areas vs. NYC). Accessible, effective HIV care is perhaps available regardless of characteristics of the NYC neighborhood in which people live, mitigating neighborhood-level disadvantage after diagnosis. Finally, publication bias may have limited the publication of previous null findings on neighborhood characteristics and HIV outcomes.[82, 83]

Being diagnosed at a facility 1 to <5 miles from one's residence was also associated with quicker suppression relative to ≥10 miles away, suggesting that proximity may be important, although interestingly persons diagnosed at facilities within one mile of their residences did not share this advantage. These were not known to be institutionalized persons, who were excluded from the analysis because their outcomes might be influenced by neighborhood and facility differently than non-institutionalized persons. Rather, perhaps facilities <1 mile from persons' residences were disproportionately (a) offices of their regular (i.e., pre-HIV-infection) primary care physicians and/or (b) selected for convenience. In either case, staff may have had less expertise in managing HIV or making effective linkages to HIV specialty care. This hypothesis is feasible if these factors are independent from patient volume and facility type, which were controlled for. Unfortunately, we did not know the mode of transportation nor time required to get to the facility, which may at least partially explain why persons <1 mile from their facilities did not experience quickest suppression. An analysis on correlates of the distance that persons with HIV in another Northeast US city, Philadelphia, travel for care found that greater patient distance from the nearest care site was associated with non-achievement of viral suppression, among persons who had been retained.[84] However, distance was not associated with progression along other parts of the continuum of HIV-related medical care, from diagnosis to retention.[10, 13, 84] That difference in the analyses (where ours followed persons from diagnosis to suppression and theirs from retention to suppression) may account for the different findings.

Limitations

As in any population-based analysis of HIV care, ours had VL data only when persons sought care, which was at their discretion. Persons in this analysis were not necessarily tested at regular intervals and may have achieved suppression sometime before it was measured in a VL test. It is not

clear whether these circumstances would have over- or underestimated our hazard ratios. However, most persons in the analysis (88%) had at least one VL test between 8 days post-diagnosis and death (Appendix 6). Among that 88%, persons diagnosed in 2006, with the most follow-up, had a median of 17 VL tests (IQR: 10-23) and the median interval between tests was 120 days (4 months; IQR: 95-182 days), while persons diagnosed in 2010 had a median of 8 tests (IQR: 5-10) and the median interval between tests was 101 days (3 months; IQR: 85-139 days). These estimates indicate that the majority of New Yorkers newly diagnosed with HIV between 2006 and 2010 were engaged in care at intervals that were both consistent with federal guidelines and sufficiently frequent to produce population-level estimates of suppression.

Persons not in care in NYC were presumed to be present and unsuppressed, although they may have moved out of NYC and become suppressed elsewhere. Non-ascertainment of outmigration is a typical limitation of local HIV surveillance data. An analysis of mobility among NYC AIDS cases who died found that males, whites, MSM, and younger persons were more likely to have left the city;[85] it is possible that the same demographic and risk groups are more likely to leave NYC shortly after HIV diagnosis and thus have undetected suppression. All of these circumstances increase the apparent time to suppression overall, and higher outmigration in some groups could result in differential underascertainment of suppression. This may have overestimated the male-female disparity in suppression rates (i.e., made the HR for males lower) but underestimated disparities by race/ethnicity and risk (i.e., decreased the HRs for white and MSM), since whites and MSM were most likely, in multivariable models, to achieve suppression.

We note that a newly diagnosed person who is in NYC but not in care and not getting blood drawn for viral load tests cannot receive ART by prescription and therefore is unlikely to be suppressed; as such, there is likely little underascertainment of suppression among persons actually in NYC. Additionally, newly diagnosed persons were known to be in NYC as recently as their diagnoses, if not at later points of care, and thus have had relatively little time to leave NYC. Further, the system of care and services, comparatively generous benefits, and large HIV-positive population in NYC make it a relatively attractive place for HIV-positive persons to live and receive care.

There are several steps between diagnosis and suppression in the continuum of care for HIV-positive persons.[10, 13] By design, this analysis did not elucidate the exact step(s) at which facility-level factors affect suppression. Other analyses have investigated the role of facility or health care services in intermediate steps in the continuum, such as time from diagnosis to linkage,[35, 86] continuous care or retention in care,[79, 80, 87] and ART use and suppression among persons in care.[88]

Characteristics measured at one level may have acted at another level. For example, poverty was measured at the neighborhood level only and was found not to be significantly associated with suppression. It is possible that there is no association between individual-level poverty, which we could not measure, and suppression, or alternatively, that individual-level poverty would in fact have been associated with suppression. This limitation is not unique to our analysis but rather is a characteristic shortcoming of multilevel analyses.[89, 90]

Strengths

This is among the first analyses in the US to investigate the influence of facility and neighborhood on HIV outcomes using surveillance data. [31, 33, 35, 87] The data were drawn from population surveillance in the largest HIV epidemic in the US, in a diverse US city. It combined data from multiple sources to assess the potential influence on viral suppression of factors beyond the individual. Mandatory electronic reporting of laboratory tests in NYC provided information about all measured VLs for all HIV-positive persons receiving care in NYC, as opposed to in a clinical trials environment, where findings can differ from those in a population setting. We filled a gap in the literature by including teenagers, who are subject to the same treatment guidelines as adults but whose young age may have contributed to slower suppression than among older persons.[78] To assign area-based characteristics to individuals, we used patient address geocoded to the Census tract, which is the gold standard for detection of public health disparities;[47] other geographic analyses of HIV care outcomes have used only counties and ZIP codes, which are much larger than Census tracts.

Conclusions

We have identified individual and facility characteristics that seem to help persons newly diagnosed with HIV to achieve viral suppression, thus improving their health and preventing ongoing HIV transmission. Those persons or health care facilities with characteristics associated with slower achievement of suppression may need more assistance after diagnosis with linkage to and retention in

care or ART prescribing and adherence. For example, black persons may benefit from more-frequent medical care and prescription of ART that permits them to become suppressed at comparable rates as whites;[15, 22, 25-27, 91] rectifying this disparity may require more equitable prescribing behavior and/or better adherence support.[92] NYC can continue to encourage HIV testing at large facilities, including hospitals, where patients have the greatest likelihood of reaching suppression quickly. We can also increase the capacity of facilities that make fewer diagnoses annually, or that are neither hospitals nor private physicians' offices, to move their patients along the continuum of care from diagnosis to suppression, even if this means ensuring effective linkage to care at another site that has cared for more HIV-positive patients. Since 2010, New York State law has required all providers to link positive patients to care, and the United States Department of Health and Human Services now encourages antiretroviral therapy for all diagnosed persons, regardless of CD4 count, which should further the improvement in suppression rates. Future studies should monitor whether facility-level disparities in suppression decrease over time, as more facilities presumably adhere to the law.

Table 2.1. Achievement of HIV viral suppression among persons newly diagnosed with HIV in New York City in 2006-2010 and followed through 2012, by individual-level characteristics

	Total	Not virologically suppressed within 12 months	Virologically suppressed within 12 months			Median time from diagnosis to suppression	
	Distribution (n)	Distribution (n)	Distribution (n)	Prevalence	*p*-value[1]	Median (IQR[2]) days	*p*-value[3]
Total	***100.0 (12,547)***	***100.0 (7,031)***	***100.0 (5,516)***	***44.0***		***245 (532)***	
Age group (years) at diagnosis					<0.0001		<0.0001
13 – 19	4.7 (590)	5.8 (405)	3.4 (185)	31.4		436 (772)	
20 – 29	27.9 (3,497)	30.9 (2,172)	24.0 (1,325)	37.9		339 (633)

Chapter 3. Multilevel analysis of individual, health care facility, and neighborhood characteristics associated with HIV virologic failure after suppression among persons newly diagnosed with HIV in New York City

Introduction

New York City (NYC) is home to more than 7% of all persons newly diagnosed with HIV in the United States (US) each year.[1, 2] Reduction of each person's HIV viral load (VL) to low or undetectable levels (e.g., ≤400 copies/mL) is called viral suppression and is typically achieved by antiretroviral therapy (ART) treatment.[4] Viral suppression slows progression of HIV disease [7] and reduces the likelihood of onward sexual transmission.[8] As few as 20% of PLWHA were thought to be suppressed in the US in the early 2000s, while today most estimates exceed 50%;[10-14] in NYC, it was 59% in 2010.[14] The US National HIV/AIDS Strategy's 2015 goal is a 20% increase in the proportion of persons virally suppressed, within several populations most affected by HIV (blacks, Hispanics, and gay and bisexual men).[9]

Epidemiologic studies have rarely examined VL over time or in terms of factors other than individual demographics and clinical characteristics. Most published population-level viral suppression estimates, including those in the HIV care continuum literature, refer only to the most recent VL measure.[10, 13] A single VL measure may not indicate maintenance of suppression (also referred to as sustained suppression).[16] The few population-based studies following individuals' viral loads over time have found that a substantial proportion do not maintain suppression long; for example, 18% of New Yorkers newly diagnosed in 2006-2009 experienced virologic failure (loss after achievement of suppression) within 12 months of suppression.[15, 17-19] While the main driver of virologic failure is poor adherence to ART, a study using NYC data found that more rapid failure after suppression was also associated with individual-level demographic characteristics, e.g., black race, younger age, female sex at birth, baseline clinical status indicators such as CD4 count and VL, and earlier calendar year of diagnosis (i.e., failure rates have declined over time).[15] Further, some of these characteristics are known mediators of adherence. Studies of virologic failure may benefit from the addition of variables describing more macro-level or structural factors, such as the characteristics of the health care facilities where people receive care and the neighborhoods where they live. For example, facility characteristics, such as

type of clinical setting, accessibility (including travel distance for patients), the support offered to patients, and physician experience have been shown to influence intermediary outcomes such as receipt of and adherence to ART, both necessary steps for achievement and maintenance of suppression.[31-34] Moreover, neighborhood factors such as lower area-level socioeconomic status have been associated with delayed initiation of treatment and excess mortality.[31, 33, 39, 43, 93] However, few studies on virologic failure have included facility or neighborhood characteristics.

Information about the characteristics associated with virologic failure is now included in many HIV surveillance registries [15, 25, 52], and these characteristics will become increasingly important to identify as more persons with HIV receive ART and achieve suppression. Thus, to examine these factors, we investigated the effect of individual, health care facility, and neighborhood characteristics on HIV virologic failure among New York City residents aged 13 years and older who were diagnosed with HIV between 2006 and 2010 and had achieved viral suppression. The results of this analysis may be used to improve public health by identifying groups of persons who, because of individual or structural factors, are vulnerable to virologic failure and who might benefit from interventions accounting for these factors to improve ART adherence.

Methods

Data sources

This retrospective analysis used data from the NYC HIV surveillance registry reported by September 30, 2013, the 2010 US Census,[54] and the 2011 American Community Survey.[55] The registry includes all persons diagnosed and reported with HIV in NYC since 2000. It gathers information by medical record review, provider report at diagnosis, and HIV-related laboratory tests, which are electronically reported to surveillance for all existing cases diagnosed and/or receiving care in NYC.

The registry included individual-level demographic and clinical information collected at the time of first report of HIV diagnosis or first VL test indicating suppression, address of residence at diagnosis, and HIV-related laboratory test results from 2006-2012 for all New Yorkers newly diagnosed with HIV and achieving viral suppression. Laboratory reports contain the test type, specimen collection date, result, and submitting provider or facility. Health care facility data from 2006-2012 were obtained from the registry and linked to cases according to the facility that conducted the first VL test indicating suppression

for each case. Finally, neighborhood data were acquired from the 2010 US Census and the 2011 American Community Survey 5-year estimates. Patient address of residence at diagnosis, obtained from the registry, was geocoded to the Census tract to link tract-level neighborhood data from the US Census and American Community Survey to individuals. Although the baseline time point for this analysis was first viral suppression, residence at diagnosis rather than at first suppression was used because Census tract-level residence data at first suppression were not available.

Population

Our analysis population was drawn from NYC residents who were newly diagnosed with HIV between 2006 and 2010, were at least 13 years of age at diagnosis, and achieved viral suppression (≤400 copies/mL) ≥31 days following diagnosis and by 12/31/2012 (N=10,232 persons). The cut-off for suppression was 400 copies/mL because this was the highest lower detectable limit of all VL assays being used during the study period.[59] Persons were then excluded from the analysis population if their death date appeared to precede their first suppression date (n=6), they had an HIV diagnosis date that was potentially misclassified (n=653; e.g., they had neither a Western blot confirmatory test within 31 days of diagnosis nor a diagnosis of acute HIV infection), the name of the facility of diagnosis or suppression was missing (n=15), their address of residence and of facility of diagnosis or suppression were equivalent, possibly indicating a homeless or institutionalized person, for whom characteristics of the neighborhood of residence might influence health outcomes differently (n=415), they were diagnosed or suppressed at a correctional facility or suppressed at a screening/diagnostic facility, possibly indicating an institutionalized person or a misclassified care facility type (n=205), or their neighborhood-level characteristics were unknown (n=11). These exclusions yielded an analytical sample of 8,927 persons (see Appendix 1).

Outcome

The outcome of interest was virologic failure, defined as having a VL ≥1,000 copies/mL or not having any VL test for 12 consecutive months. The 1,000-copy cutoff permitted a modest increase in VL above 400 that would not necessarily signal virologic failure but rather perhaps just a "blip."[60] Additionally, risk of HIV transmission from a person with VL up to 1000 is low.[8, 61] Requiring VL tests every 12 months in order to be classified as maintaining suppression ensured at least minimal engagement in care, as quarterly testing is recommended for most persons with HIV.[70] The 12-month

requirement also provided an endpoint for persons who dropped out of care, since care is required to detect any VL, and it was not reasonable to assume that persons who dropped out of care in NYC would remain suppressed. Censoring occurred at whichever came earlier: death or the end of the follow-up period. Follow-up time was calculated as the number of days from the date of first viral suppression after HIV diagnosis to the earliest of these dates: virologic failure, death, or 12/31/2012.

Covariates

Individual-level variables

Most of the demographic characteristics in our analyses were shown in previous analyses to be associated with virologic failure among newly diagnosed New Yorkers who had achieved viral suppression.[15] Demographic characteristics (age, sex at birth, race/ethnicity, area of birth), HIV transmission risk (also referred to as transmission categories), viral suppression date, viral loads, CD4 counts, and address of residence at diagnosis were acquired from the NYC HIV surveillance registry.

Age at viral suppression was calculated from birth date to date of first suppression and categorized as 13-19, 20-29, 30-39, 40-49, 50-59, and 60+.[2] Sex at birth was specified as collected, male or female. Race was collected as white or Caucasian, black or African American, Asian or Pacific Islander, and Native American. Ethnicity was collected as Hispanic, non-Hispanic, or unknown. Race and ethnicity were combined into a single variable in which all persons of Hispanic ethnicity were classified as Hispanic, and non-Hispanics were classified as black, white, or other non-Hispanic race (which included Asians and Pacific Islanders, Native Americans, and multiracial persons).[15] Area of birth was collected as country of birth when available or region of birth and categorized as born in the US, US dependency (e.g., Puerto Rico), foreign country, or unknown place of birth.[68]

HIV transmission risk category was based on pre-diagnosis risk behaviors documented in the medical record and/or self-reported at the time of diagnosis (e.g., injection drug use, male-male sex) and the sex, HIV status (e.g., HIV-positive), and risk (e.g., injection drug use) of the pre-diagnosis heterosexual-sex partners reported by the case.[69] This information was combined into hierarchical categories: injection drug use, men who have sex with men, heterosexual sex, and other or unknown (which included perinatal transmission).[15] To be classified as most likely having acquired HIV through heterosexual sex, persons must have reported pre-diagnosis sex with a partner of the other sex who was

HIV-infected, had injected drugs, or had received blood products. In addition, females could be classified as heterosexual if they had probable heterosexual transmission noted in their medical record, reported sex with a male and no history of drug injection, or had any one of several behaviors associated with heterosexual transmission (history of prostitution, multiple sex partners, sexually transmitted disease, crack/cocaine use, or sex with a bisexual male).[2]

CD4 count (if any) at suppression was based on the first CD4 count within 31 days before or after suppression and categorized as 0-199, 200-349, 350-499, and ≥500 cells/mL.

Health care facility-level variables

Characteristics of the facility of first suppression include annual HIV patient volume, type, and patient-to-provider distance, all of which could be ascertained or calculated based on information in the NYC HIV surveillance registry. HIV patient volume was collected as number of HIV-positive patients cared for annually, based on persons receiving a VL or CD4 test (as reported to surveillance) at that facility in the year of the patient's viral suppression, and categorized as <250, 250-999, 1,000-1,999, and ≥2,000 patients per year.[33, 73] Facility type was categorized as hospital, private physician (also referred to as private practice), other outpatient facility, and other or unknown (<10 persons had a known facility but unknown type), as potential indicators of the availability of ancillary services (at the first and third types) [32]. These two variables of HIV patient volume and facility type were further combined (see Appendix 7), with patient volume dichotomized as <1,000 (small) and ≥1,000 (large), to better capture underlying concepts. Patient-provider distance was calculated as the distance in miles using the most direct street route from patient residence to the facility where suppression was first detected (based on the XY coordinates of each) using Network Analyst in ArcMap 10.0 (ESRI, Redmonds, CA) and a network dataset of NYC streets that is used within the NYC Department of Health and Mental Hygiene (see Appendix 4). This distance was categorized as <1 mile, 1-<5 miles, 5-<10 miles, and ≥10 miles.

Neighborhood-level variables

Analyses included two Census tract-level SES measures from 2011 American Community Survey (ACS) 5-year estimates; this is the recommended source for such statistics because the 2010 decennial census did not collect them.[74] These measures have previously been associated with HIV or sexually transmitted infections or HIV outcomes and include percent of residents with incomes under the federal

poverty threshold[31, 33, 39, 40, 47, 75] and percent unemployed among residents aged 16 years and older.[31, 39, 41, 75] Census 2010 provided data on percent of non-Hispanic black residents.[74] The values for percent unemployed and percent black were divided by 10 and entered into a proportional hazards regression as continuous variables with every unit representing a 10-percentage-point difference. Poverty was categorized as 0 to <10% (low-poverty), 10 to <20% (medium-poverty), 20 to <30% (high-poverty), and 30 to 100% (very-high-poverty), based on recommendations of the NYC health department.[76] These particular neighborhood-level variables (poverty, unemployment, and black race) have been used together previously.[43]

Statistical analysis

Descriptive statistics were calculated for selected characteristics at the individual, facility, and neighborhood levels and presented for the overall population and according to virologic failure status within 12 months (365 days) of suppression. Association between each variable and virologic failure within 12 months was measured using Chi-squared tests. Differences in median days to failure by the end of the follow-up period were determined using Mann-Whitney U test.

Kaplan-Meier curves showing the number of days from suppression to failure were generated by key individual, health care facility, and neighborhood characteristics. Log-rank tests were used to indicate differences between groups.

Cox proportional hazards regressions estimated the association of individual, facility, and neighborhood-level factors with failure in crude and adjusted models. Robust sandwich estimation of the standard errors was used to account for correlations of individual outcomes within either facility of suppression or neighborhood (Census tract).[62, 63] We fit several models after estimating unadjusted rates for virologic failure for each individual, facility, and neighborhood characteristic. We began by estimated hazards of virologic failure for each individual characteristic after adjustment for all other individual characteristics (i.e., without any facility or neighborhood characteristics). Next, we fit models to estimate the hazards for each facility and each neighborhood characteristic, after controlling for individual characteristics. Specifically, because we were exploring the role of structural or macro-level variables in virologic failure, each variable at the facility or neighborhood level was entered, one at a time, into a model with all individual characteristics. Finally, two models were fitted to estimate the adjusted hazards for 1) all individual and facility characteristics and 2) all individual and neighborhood characteristics.

Model fit was compared with a X^2 test according to difference in -2LL and degrees of freedom (see Appendix 7).

All analyses were conducted using SAS 9.2 (SAS Institute, Cary, NC). Ethical approval for the analysis was granted by the Institutional Review Boards of Lehman College of the City University of New York and of the New York City Department of Health and Mental Hygiene.

Results

Descriptive statistics

Of 8,927 New Yorkers newly diagnosed with HIV in 2006–2010 and achieving viral suppression, approximately three-quarters were 20-49 years old (78.9%), male (74.2%), and black or Hispanic (79.9%; Table 3.1). Approximately half were US-born (52.7%), were men who have sex with men (46.8%), and had CD4 counts ≥350 at suppression (49.6%). Almost one-fifth (18.2%) of the population experienced failure within 12 months of suppression (Table 3.1). Compared to persons who did not experience failure within 12 months of suppression, those who did were more likely to be younger, female, black or Hispanic, born in a US dependency, and injection drug user or heterosexual (all *p*-values <0.001).

Virologic failure occurred at a median of 728 days, i.e., approximately 2 years after achievement of suppression (Table 3.1). Failure happened most quickly among persons who were younger vs. older, black or Hispanic vs. white, born in the US or a US dependency vs. foreign-born, or injection drug user vs. other risk categories. Failure was also quicker among persons who had suppressed in later vs. earlier calendar years (but likely, in part, as an artifact of the shorter follow-up time for those suppressing in later years), had higher vs. lower CD4 counts at suppression, or first achieved suppression in large outpatient facilities or large private practices vs. smaller or other facility types. Differences in time to failure were most prominent by CD4 count (827 days among persons with CD4 0-199 vs. 599 among 500+). These differences were confirmed by the Kaplan-Meier survival curves (by CD4 count, *p*=0.0074; Figure 3.1a).

Approximately half of the population first achieved suppression in facilities that cared for ≥1,000 HIV-positive persons (52.7%), were hospitals (54.7%), and were 1 to <5 miles from their home (52.5%; Table 3.2); and lived in neighborhoods where ≥20% of the population was below the poverty threshold (i.e., high or very high poverty; 58.0%). Among persons in the analysis population, the mean

neighborhood-level unemployment rate was 10.7% (for reference, in comparison, the citywide rate was 9.5%[55]), and the mean neighborhood-level percent black was 33.3% (the citywide rate was 22.8%[94]).

When compared to persons who maintained suppression, those who experienced failure within 12 months of first suppression were most likely to have been first suppressed at large hospitals or small outpatient facilities and to be residents of higher-poverty neighborhoods (Table 3.2). Differences in failure by facility type and patient volume as well as by neighborhood poverty level were clearly apparent in Kaplan-Meier survival curves (all $p<0.0001$; facility type and patient volume and neighborhood poverty shown in Figures 3.1b-3.1c).

Modelling individual characteristics

Table 3.3 presents the unadjusted and adjusted HRs for individual characteristics on HIV virologic failure among persons newly diagnosed with HIV and achieving viral suppression in NYC. The unadjusted HRs show that persons who were younger, female, black or Hispanic, born in the US or a US dependency, not men who have sex with men, and who had a CD4 count ≥500 cells/mL experienced rates of failure that were elevated at least 10% (range 11% to 95%).

After adjustment for individual characteristics only, the rate of virologic failure remained higher among younger persons, blacks and Hispanics, US- and US-dependency born persons, heterosexuals and injection drug users, and persons with CD4 counts ≥500 cells/mL at suppression, compared with others. For example, rates were between 21 and 101% higher for persons 13-49 years old relative to those 60 and older (e.g., 20-29 years old, 56%[95%CI=1.32-1.85]). These findings remained nearly identical when adjusting for either facility or neighborhood characteristics (adjusted hazard ratios [AHRs] 2 and 3 in Table 3.3).

Modelling facility and neighborhood characteristics

Table 3.4 presents the unadjusted and adjusted HRs for facility and neighborhood characteristics on HIV virologic failure among persons newly diagnosed and achieving suppression with HIV in NYC. The unadjusted HRs show higher failure rates among persons suppressed at hospitals and small outpatient facilities, and among residents of neighborhoods with higher proportions of residents who were poor, unemployed, or black, compared with others.

Most facility-related findings remained the same after adjustment for individual characteristics alone, and then individual characteristics as well as either all facility or all neighborhood characteristics.

However, persons suppressed at small private practices or at small facilities other than hospitals, outpatient facilities, or private practices, became as likely as persons in large hospitals to experience failure (when controlling for all individual and facility characteristics, AHR[95%CI]=0.94[0.81-1.08]). The model with all individual- and facility-level variables had the best fit (-2LL: 64,069; p<0.0001 vs. the model with all individual-level variables only; see Appendix 7). Among neighborhood characteristics, only high or very high poverty remained associated with failure in models adjusted for individual characteristics (e.g., AHR=1.19[95% CI=1.06-1.34] for very-high vs. low poverty).

Discussion

Virologic failure after suppression was experienced more quickly among persons who were younger, black or Hispanic, US- or US-dependency-born, non-MSM, and diagnosed in earlier years, and among persons with higher CD4 counts at suppression, after controlling for facility or neighborhood characteristics. Similarly, persons receiving care at facilities that were not large outpatient facilities or large private practices, and residents of higher-poverty neighborhoods, had higher failure rates than others, after controlling for individual and other facility or neighborhood characteristics.

Our findings about individual, facility, and neighborhood characteristics associated with failure were largely consistent with the literature [15, 31-34, 39] and also provided unique information about teenagers. Several studies have examined the influence of age on suppression and failure among persons 18 or 21 years of age and older.[15, 95, 96] However, few studies of virologic failure have included younger teens. In our analysis, persons in the 13-19-year age group (28% of whom were under 18; see Appendix 7) had the highest rate of failure. Teenagers have been found to have lower rates of retention in care and ART adherence.[77, 78] Higher failure rates among persons in care at facilities other than large outpatient facilities or large private practices possibly may be because those facilities were less likely to provide services supporting retention, adherence, and case management (in some cases, due to their smaller size), which have been shown to facilitate retention in care;[79, 80] their providers were less likely to adhere to HIV-related care recommendations;[81] or the patients had clinical, behavioral, or socioeconomic characteristics not captured in our models, such as addiction, other mental illness, or individual poverty, that left them less able to maintain high adherence even if they were able to see a physician, obtain ART, and achieve suppression. The potential explanations of individual poverty

or of mental illness (if so disabling as to qualify someone for public health insurance) would be consistent with previous findings that persons with private insurance were more likely to sustain viral suppression than persons insured by Medicaid or Medicare, or who were uninsured.[20] Our analysis was unable to identify which of these factors might account for the higher failure rates among persons achieving suppression even at large hospitals, many of which are Designated AIDS Centers. Our findings about neighborhood-level poverty being associated with failure were consistent with previous studies on neighborhood-level socioeconomic factors and care-related outcomes[31, 33, 38-42]. However, percentages of neighborhood residents who were black or unemployed were not associated with failure after controlling for neighborhood-level poverty. This is consistent with previous findings that neighborhood-level poverty, rather than other factors such as neighborhood-level racial/ethnic makeup or unemployment rates, was the socioeconomic indicator most predictive of health disparities.[47] This also suggests that the many resources available for low-income PLWHA in NYC to receive care, medication, and other forms of support, may not entirely eliminate the effects of poverty on HIV-related health outcomes.

Prior literature found that shorter distance to the nearest HIV care site was associated with achievement of viral suppression among persons retained in care.[84] However, we found no association between distance from a person's residence to the facility at which s/he was first suppressed (i.e., where s/he was receiving care) and time from first viral suppression to failure. The extensiveness of NYC's systems of HIV care and public transit,[97] coupled with New York State's generous benefits and services for persons with HIV,[98] may have helped render patient-provider distance irrelevant to virologic failure – even as a relationship between neighborhood-level poverty and failure persisted.

In summary, adding facility and neighborhood variables to population-level models of virologic failure after suppression did not change the individual characteristics associated with failure but did permit the identification of several structural (i.e., facility and neighborhood) factors also associated with failure. These structural factors may be useful targets for interventions aiming to increase maintenance of suppression among persons with HIV, or may be used to indicate persons who would benefit from additional support to maintain suppression, thereby improving their health and reducing transmissibility.

Limitations

Our analysis was subject to limitations typical of population-based, multilevel, geographic, or surveillance-based analyses. Namely, some people's VL was measured only at irregular intervals, and outmigration could not be directly ascertained. Data on several factors that may influence maintenance of suppression were not available in the HIV surveillance registry. Additionally, it was difficult to identify the level at which certain characteristics influenced the outcome. Finally, findings may have been sensitive to the geographic level of aggregation, i.e., Census tract, or to residential moves between diagnosis and suppression. These factors may have caused over- or underestimation of hazard ratios.

Our analysis had VL data only when persons sought care, which was at their discretion and not necessarily at regular intervals. Persons may have experienced virologic failure sometime before it was measured in a VL test or after dropping out of care. Persons not in care in NYC for up to 12 months after a suppressed VL were presumed to be present and suppressed, although prior to the 12-month mark they may have experienced failure or moved out of NYC and maintained suppression elsewhere. It is not clear whether irregular testing and unascertained outmigration would have increased or decreased our hazard ratios. However, the majority of New Yorkers newly diagnosed with HIV between 2006 and 2010 were engaged in care at intervals that were both consistent with federal guidelines and sufficiently frequent to produce population-level estimates of suppression. Specifically, among newly diagnosed persons with at least one VL test between diagnosis and death, persons diagnosed in 2006, with the most follow-up, had a median of 17 VL tests (IQR: 10-23) and the median interval between tests was 120 days (4 months; IQR: 95-182 days), while persons diagnosed in 2010 had a median of 8 tests (IQR: 5-10) and the median interval between tests was 101 days (3 months; IQR: 85-139 days). Additionally, there is likely to be little under-ascertainment of failure among persons in NYC, for several reasons. First, a recently diagnosed and virally suppressed person with no subsequent blood draw for VL tests cannot receive ART by prescription and therefore is unlikely to maintain suppression.[72] Second, a newly suppressed person was in NYC as recently as his/her suppression date, and thus, had relatively little time to leave NYC. Third, the system of care and services, generous benefits, and large HIV-positive population in NYC have long made it a relatively attractive place for HIV-positive persons to live and receive care; this likely promotes retention and suppression.

Because the HIV surveillance system provided the individual-level data in our analysis, information about several individual factors that may influence the maintenance of suppression were not available. Specifically, mental illness and addiction that are not well-controlled may affect a person's ability to adhere to ART, potentially triggering failure after suppression, but mental health and substance use (other than injection drug use) are not necessarily well-documented in the medical record at the facility diagnosing HIV nor well-ascertained by surveillance. Further, information about ART adherence, the primary driver of maintenance of suppression, was not available.

Characteristics measured at one level in our models may have acted at another level. For example, poverty was measured at the neighborhood level only and was found to be significantly associated with virologic failure. It is possible that this association was present only because there is an association between neighborhood- and individual-level poverty, which was not measured, and failure (and individual- and neighborhood-level poverty are correlated), or alternatively, that individual-level poverty would not in fact have been associated with failure. This limitation is not unique to our analysis but rather is characteristic of multilevel analyses.[89, 90]

As in any geographic analysis, our findings may have been subject to the modifiable areal unit problem, meaning they were sensitive to the geographic level (Census tract) at which patient residence and facility location were measured.[99-101] Analyses at other levels would have grouped people differently, e.g., in smaller or larger areas, or with different geographic boundaries that would have resulted in different aggregations of people, and may have produced different findings. Further, because of the edge effect, adjacent or nearby Census tracts may have had cross-boundary similarities and influences, largely due to the movement of people across multiple Census tracts.[102, 103] This could dilute the effect of differences across neighborhoods.

Because Census tract-level residence information at first viral suppression was not available, we assumed that the neighborhood characteristics of a person's residence at diagnosis were comparable to those at first suppression. However, more than 21% of persons in our analysis may have changed Census tract of residence between diagnosis and suppression. Studies have shown that persons who move typically go to similar neighborhoods.[104] However, in the population in our analyses, many of the 21% who moved went to Census tracts with different characteristics, e.g., poverty level, than the Census

tracts they were living in at diagnosis. It is not possible to determine whether this misclassification of persons' neighborhood-level variables was differential or non-differential (see Appendix 7).

Strengths

This is among the first analyses in the US to investigate the influence of facility and neighborhood on HIV outcomes using surveillance data. [31, 33, 35, 87] The data were drawn from population surveillance in the largest HIV epidemic in the US, in a diverse US city. The analysis combined data from multiple sources to assess the potential influence on virologic failure of factors beyond the individual. Mandatory electronic reporting of laboratory tests in NYC provided information about all measured VLs for all HIV-positive persons receiving care in NYC, as opposed to in a clinical trials environment, where findings can differ from those in a population setting. To assign area-based characteristics to individuals, we used patient address geocoded to the Census tract, which is the gold standard for detection of public health disparities;[47] other geographic analyses of HIV care outcomes have used only counties and ZIP codes, which are much larger than Census tracts. Due to NYC's heterogeneity, the smaller geographic unit (tract) was preferable. We filled a gap in the literature by including teenagers, who are subject to the same treatment guidelines as adults but whose age may have contributed to quicker virologic failure than among older persons.[78] The survival analysis method permitted the analysis of VL data over a long period of time and did not require multiple VL tests as an inclusion criterion.

Conclusions

Our findings suggest that persons with HIV who are younger, black or Hispanic, US- or US-dependency-born, non-MSM, or have higher CD4 counts at suppression; or who seek care at facilities other than large outpatient facilities or large private practices; or who live in high- or very-high-poverty neighborhoods; were more likely to experience virologic failure. These populations may need more assistance after viral suppression in the areas of retention in care or ART adherence. These facility- and neighborhood-level effects were found even in NYC, the setting for this analysis, i.e., a large, densely populated city with extensive systems of high-quality HIV care, social services, and public transportation. It is possible that the effects would have been even larger in a setting other than NYC that may not have been as well-resourced vis-à-vis medical facilities and transportation systems. It is possible that residents of poorer neighborhoods in NYC might benefit from even better care that permitted them to maintain suppression at comparable rates as residents of wealthier neighborhoods; rectifying this disparity may

require targeted adherence support services or additional general poverty alleviation. Further investigation is needed to understand why lower rates of failure were seen among patients at large outpatient facilities and large private providers, which serve a minority of New Yorkers with HIV. Additional investigation would also be valuable to suggest how large hospitals – many of which are Designated AIDS Centers, and which detected the first viral suppression for 43% of newly diagnosed New Yorkers – can better support their patients in maintaining suppression.

Table 3.1. HIV virologic failure[1] within 12 months after first viral suppression among persons newly diagnosed with HIV in New York City in 2006-2010 and followed through 2012, by individual-level characteristics

	Total	No virologic failure* within 12 months of suppression	Virologic failure[1] within 12 months of suppression			Median time from suppression to failure	
	Distribution (n)	Distribution (n)	Distribution (n)	Prevalence	*p*-value[2]	Median (IQR[3]) days	*p*-value[4]

Chapter 4. The association of perceived neighborhood social cohesion with achievement of HIV viral suppression among persons recently diagnosed with HIV and interviewed in New York City

Introduction

New York City (NYC) is home to more than 7% of all persons newly diagnosed with HIV in the United States (US) each year.[1, 2]. It is recommended that persons newly diagnosed with HIV have their viral load (VL) measured as soon as they begin HIV-related medical care and then at least every six months.[3] HIV infection typically is followed by a very high VL (e.g., >100,000 copies of HIV RNA per milliliter of blood) that eventually declines to lower levels that vary by individual. Further reduction of HIV VL to low or undetectable levels (e.g., ≤400 copies/mL) is referred to as viral suppression. Although a small percentage of persons (i.e., "elite controllers") is able to achieve suppression without treatment, most persons achieve suppression by being treated with antiretroviral therapy (ART).[4] Provided that the virus is sensitive to the multi-drug regimen chosen and the person is adherent, ART helps a person achieve suppression quickly (within 24 weeks) and durably.[5, 6]

Viral suppression not only slows progression of HIV disease [7] but also reduces the likelihood of onward sexual transmission.[8] As few as 20% of PLWHA were thought to be suppressed in the US in the early 2000s, while today most estimates exceed 50%;[10-14] in NYC, it was 59% in 2010.[14] In 2010, the US National HIV/AIDS Strategy set as a goal a 20% increase by 2015 in the proportion of persons in populations most affected by HIV (blacks, Hispanics, and gay and bisexual men) who are virally suppressed.[9] Updated national HIV treatment guidelines now recommend that all persons with HIV be offered ART.[3] However, until recently, it was recommended that persons begin ART only once immunocompromised, making immune status at diagnosis a key driver of treatment decisions. Although retention in care and ART are the main drivers of viral suppression, more rapid achievement of suppression has also been associated with individual-level demographic characteristics (e.g., older age,[13, 15, 20] male sex,[21-23] and non-black racial/ethnic category [13, 24-28]), and baseline clinical status indicators (e.g, CD4 count and VL[15, 29, 30]).

Studies focusing on individual-level factors affecting viral suppression may benefit from the addition of social and structural variables that have previously been associated with health and health-

seeking behavior, such as perceived neighborhood social cohesion. Lower perceived neighborhood social cohesion has been associated with lower primary care use among older urban adults.[44] Lower care use may, in turn, influence the time from HIV diagnosis to viral suppression because ART and VL testing are offered exclusively in the context of medical care visits. Low cohesion has also been associated with lower condom use and higher sexually transmitted infection (STI) rates among urban adolescents and young adults.[45, 46] Because STI can increase VL, social cohesion may affect viral suppression through condom use and STI rates. However, the association of social cohesion with HIV outcomes has not been examined. The availability of data on social cohesion for a sample of New Yorkers recently diagnosed with HIV allows the investigation of the effect of perceived neighborhood social cohesion on achievement of viral suppression among NYC residents who were diagnosed with HIV between 2006 and 2012 at ≥13 years of age. Findings could potentially be helpful in the development of interventions to increase suppression rates by accounting for a person's perception of neighborhood social cohesion and determining which persons may need additional support to achieve suppression.

Methods

Data sources

This retrospective analysis used data from the NYC HIV surveillance registry, the NYC arm of the CDC-coordinated Case Surveillance-Based Sampling project (CSBS),[53] and the 2007-2011 American Community Surveys.[55] The registry includes all persons diagnosed and reported with HIV in NYC since 2000 and all persons with AIDS since 1981. It gathers information by medical record review, provider report at diagnosis, and HIV-related laboratory tests, which are electronically reported to surveillance for all existing cases receiving diagnosis and/or care in NYC. Individual-level data acquired from the registry included demographic and clinical information collected at the time of first report, ZIP code of residence at diagnosis, and HIV-related laboratory test results from January 1, 2006, to June 30, 2014. Laboratory reports contain the test type, specimen collection date, result, and submitting provider or facility. Reports on existing cases are added to their surveillance registry record; reports not matching an existing case are sent out for field investigation to confirm the diagnosis and collect other registry data. All registry data were reported as of September 30, 2014, allowing a three-month reporting lag for laboratory tests performed through June 30, 2014.

CSBS is a surveillance activity that involves conducting in-person interviews and medical record reviews for a stratified random sample of persons from the registry. CSBS data are stored outside of the registry. Data from CSBS used for this analysis included individual-level information on household income, number of persons who depended on that income (a proxy for family size), highest educational level completed, and three questions aggregated to develop an index of perceived neighborhood social cohesion, as has been done previously.[45, 46] These CSBS variables were obtained from the interview portion of the 2012-2014 cycles of the study and recorded in the CSBS database by April 15, 2015.

Finally, neighborhood poverty statistics at the level of ZIP code tabulation area (ZCTA) were acquired from the 2011 American Community Survey 5-year estimates based on the 2007-2011 surveys. ZIP codes are a system of delineating areas for postal service, and most people know the ZIP code of their residence, while ZCTAs are geographic areas used by the American Community Survey as close geographic approximations of ZIP codes.[105] ZIP codes, which in NYC are typically larger than Census tracts but smaller than congressional districts and counties, were the smallest readily available geographic unit of analysis. Neighborhood poverty statistics were linked to cases through the ZIP code of patient residence at diagnosis.

Population

CSBS sampled 800 persons from the HIV surveillance registry across three annual sample cycles (200 persons in the 2012 cycle, 300 in 2013, and 300 in 2014). Each cycle's sample was stratified by diagnosis year to oversample persons diagnosed in more recent years and limited to persons ≥18 years of age as of the sample date. NYC residents who were interviewed for CSBS in 2012-2014, newly diagnosed with HIV between 2006 and 2012, and ≥13 years of age at diagnosis (which was potentially several years prior to the sample date) were eligible for the analysis. However, among the 294 persons located and interviewed for CSBS in 2012-2014, many were excluded: those who were not newly diagnosed with HIV between 2006 and 2012 and ≥13 years of age at diagnosis (n=152), did not have an NYC ZIP code of residence at diagnosis (n=9), died within 31 days after diagnosis (n=0), did not have a Western blot confirmatory test within 31 days post-diagnosis *and* were not diagnosed during acute HIV infection (i.e., their true diagnosis date was uncertain; n=6), had a suppressed (≤400 copies/mL) viral load ≤31 days after diagnosis (which suggests a misclassified diagnosis date; n=11), or did not respond to all

three questions about perceived neighborhood social cohesion (n=24). These exclusions yielded an analytical sample of 92 persons (see Appendix 2).

Outcome

The outcome of interest was the first suppressed VL (≤400 copies of HIV RNA/mL plasma) after HIV diagnosis. The cut-off was 400 copies/mL because this was the highest lower detectable limit of all VL assays in use during the study period.[59] Persons were censored at death or the end of the follow-up period, whichever came earlier. Follow-up time was calculated as the number of days from the date of HIV diagnosis to suppression, death, or 6/30/2014, whichever came first. There was no minimum required follow-up time. In addition to measuring this outcome as time-to-event, it was also measured dichotomously as having or not having achieved suppression within 12 months of diagnosis.

Treatment guidelines evolved during the analysis period but recommended that VL tests were conducted 2-4 times per year after HIV diagnosis. However, some persons with HIV may have had infrequent or no VL tests after diagnosis, because they were never linked to HIV-related medical care, they sought care infrequently, or their physician did not test their VL at every care visit. Any persons not known to be dead and with no suppressed VL (including persons with infrequent or no VL tests) were presumed not to be suppressed and contributed follow-up time as long as they were alive.

Independent variable

Perceived neighborhood social cohesion was calculated from participant agreement with three statements in the CSBS interview about trust, closeness, and helpfulness between neighbors, using a scored 1-4 Likert scale (see Appendix 8). [45, 46] Responses were summed to yield a score ranging from 3 to 12. Scores were dichotomized near the median, a natural break, placing approximately equivalent numbers of persons in each category.[46] The majority of scores were 6, 9, or 12 (>20% each), and 48% of persons had scores of 3-8 (see Appendix 8 for additional details, including results of our analyses were cohesion to have been classified as a three-level variable). Perceived neighborhood social cohesion was classified as low for persons with scores of 9-12 and high for persons with scores of 3-8; lower scores indicated agreement with positive statements about the neighborhood.

Covariates

Individual characteristics and neighborhood poverty were treated as potential confounders based on previous studies.[15, 31, 33] Demographic characteristics (age, sex at birth, race/ethnicity, country of

birth), HIV transmission risk (also referred to as transmission category), diagnosis date, viral loads, CD4 counts, and ZIP code of residence at diagnosis for calculation of neighborhood-level poverty were extracted from the NYC HIV surveillance registry. Estimated poverty status (at the individual/family level, based on household income) was calculated from CSBS data.

Age at HIV diagnosis was calculated from birth date and date of diagnosis and dichotomized as 13-29 years old and 30+.[2] Sex at birth was classified as male or female. Race (white or Caucasian, black or African American, Asian or Pacific Islander, and Native American) and ethnicity (Hispanic, non-Hispanic, or unknown) were collected through two questions and combined into a single variable that was dichotomized as: black or Hispanic, and other for those of other race/ethnicity. Country of birth was collected as country of birth when available or region of birth and categorized as born in the US or a US dependency (e.g., Puerto Rico), or a foreign country.

HIV transmission risk category was based on the self-reported pre-diagnosis risk behaviors of the case (e.g., injection drug use, male-male sex) and the sex, HIV status (e.g., HIV-positive), and risk (e.g., injection drug use) of the pre-diagnosis heterosexual sex partners reported by the person (which could indicate high-risk heterosexual risk).[69] This information was combined into hierarchical, mutually exclusive categories for the case: injection drug use (IDU), men who have sex with men (MSM), heterosexual sex, and other or unknown (which included perinatal transmission),[15] and these categories were then combined into three final groups: MSM, heterosexual, or other or unknown (which included injection drug users). To be classified as a heterosexual male or female, persons must have reported pre-diagnosis sex with a partner of the other sex who was HIV-infected, had injected drugs, or had received blood products. In addition, females only could be classified as heterosexual if they had probable heterosexual transmission noted in their medical record, reported sex with a male and no history of drug injection, or had any one of several behaviors associated with heterosexual transmission: history of prostitution, multiple sex partners, sexually transmitted disease, crack/cocaine use, or sex with a bisexual male.[2]

For analytic purposes, the year of diagnosis was determined from the earlier of physician diagnosis date or positive Western blot test result and grouped as 2006-2009 and 2010-2012. These were two approximately equal groups of years divided at a point when suppression became more likely

for everyone because of new HIV drug approvals and updated guidelines that encouraged earlier treatment initiation; also, few CSBS participants (n=6) were diagnosed in 2006 or 2007. CD4 count (if any) at diagnosis (i.e., within 3 months of diagnosis) and year of diagnosis vis-à-vis treatment guidelines were used to estimate treatment eligibility and as a proxy for receipt of ART, on the presumption that the majority of persons reaching the federal treatment threshold would receive ART. Treatment-eligible persons included those diagnosed in 2006-2007 with CD4<200, diagnosed in 2008-2009 with CD4<350, or diagnosed in 2010-2012 with CD4<500, reflecting changing treatment guidelines that increased the CD4 count at which ART initiation was recommended.[70-72] All other persons, including those with no reported CD4 counts, were not known to be eligible and were classified as not eligible.

Analyses included neighborhood-level poverty, defined as percent of residents in a ZIP code with incomes under the federal poverty threshold, from 2011 American Community Survey 5-year estimates.[74] We used this source because the 2010 decennial census did not collect poverty information, and because ZIP code of residence was collected (by the surveillance registry) at diagnosis. For those reasons, the 2011 American Community Survey 5-year estimates had the largest overlap with the diagnosis period (2006-2012). Because lower neighborhood-level socioeconomic status (SES) may be associated with both perceived neighborhood social cohesion and viral suppression, it was controlled for when exploring the relationship between perceived neighborhood social cohesion and suppression. The neighborhood poverty measure that we used has been associated with HIV and STI incidence and prevalence and HIV outcomes in the US and Canada.[31, 33, 39, 40, 47, 75] Neighborhood poverty was specified as <20% (i.e., <20% of residents had incomes below the federal poverty threshold; these were low- or medium-poverty neighborhoods) or ≥20% (high- or very-high-poverty), based on the four-category classification used by the NYC health department that this analysis collapsed into two categories.[76]

Estimated poverty status (at the individual/family level) was calculated based on responses in CSBS to questions about household income (which was collected in intervals) and number of persons who depended on that income. These were compared with US Census Bureau weighted average poverty thresholds for 2013 by size of family unit, and then classified as below the poverty threshold (and thus “poor”) or above (“non-poor”) (see Appendix 9 for details).[106]

Statistical analysis

Descriptive statistics for selected individual and neighborhood characteristics were calculated and presented for the overall population and according to suppression status within 12 months of diagnosis. Significance of associations between each variable and achievement of suppression within 12 months was assessed using Chi-square tests. The Mann-Whitney U test was used to ascertain differences in median days to suppression by the end of the follow-up period. The Spearman correlation coefficient was obtained to assess whether the dichotomized variable of perceived neighborhood social cohesion and neighborhood-level poverty were too correlated (i.e., $r>0.5$) to be in the same model.

Kaplan-Meier curves showing the number of days from diagnosis to suppression were generated by key individual and neighborhood characteristics, and log-rank tests were used to measure differences between groups.

We used Cox proportional hazards regressions to estimate the association of individual and neighborhood factors with suppression in crude and adjusted models. Because of the small sample size, we did not account for correlations of individual outcomes within neighborhood (ZIP code).[62, 63] Unadjusted models were fitted to estimate the unadjusted hazards of viral suppression for each individual and neighborhood characteristic. In addition, several multivariable models were fitted, striving for parsimony given the small sample size. Our final model included age at HIV diagnosis, sex at birth, race/ethnicity, year of HIV diagnosis, and ART eligibility, for consistency with previous models of viral suppression,[15] as well as perceived neighborhood social cohesion and neighborhood-level poverty.

All analyses were conducted using SAS 9.2 (SAS Institute, Cary, NC). Ethical approval for these analyses was provided by the Institutional Review Boards of Lehman College of the City University of New York and of the NYC Department of Health and Mental Hygiene.

Results

Descriptive statistics

Of 92 New Yorkers newly diagnosed with HIV in 2006–2012 and interviewed by CSBS, approximately three-quarters were male (72.8%), and black or Hispanic (82.6%; Table 4.1). More than half were ≥30 years old (66.3%), born in the US or a US dependency (68.5%), MSM (51.1%), diagnosed in 2010-2012 (54.3%), not eligible to receive treatment based on CD4 count and diagnosis year (53.3%),

poor (60.9%), perceiving low neighborhood social cohesion (52.2%), and residents of high- or very-high-poverty neighborhoods (57.6%).

Sixty-five percent of the population achieved suppression within 12 months of diagnosis (Table 4.1). Suppression rates at 12 months were lower among persons who were younger (45.2% of persons 13-29 years old achieved suppression vs. 75.4% of persons ≥30), black or Hispanic (59.2% vs. 93.8%), born in the US or a US dependency (57.1% vs. 82.8%), and not eligible for treatment (46.9% vs. 86.0%; all *p*-values<0.05). Differences in suppression at 12 months between persons reporting low cohesion (60.4%) and high cohesion (70.5%) were not significant (p=0.31).

Almost the entire population (95.7%) achieved viral suppression by 6/30/2014 (not shown), in a median of 180 days (Table 4.1). Suppression happened least quickly among persons who were younger (median=377 days), black or Hispanic (203 days), born in the US or a US dependency (218 days), not known to be eligible for treatment (372 days), or who had low perceived neighborhood social cohesion (204 days; all *p*-values <0.05). Differences were most prominent by age (median=164 days among persons ≥30 years old vs. 377 days among 13-29) and treatment eligibility (159 days among eligible vs. 372 days among not eligible). Kaplan-Meier survival curves demonstrated the lack of difference in achievement of suppression between persons with low and high perceived neighborhood social cohesion (p=0.95; Figure 4.1a), the difference between persons eligible and not eligible for treatment (p<0.01; Figure 4.1b), and the lack of difference between residents of high- or very-high-poverty vs. low- or medium-poverty neighborhoods (p=0.46; Figure 4.1c).

The Spearman correlation coefficient between perceived neighborhood social cohesion and neighborhood-level poverty was 0.24 (analysis not shown in tables), indicating a low correlation, and thus, suggesting that they capture independent constructs.

Unadjusted and adjusted models

Table 4.2 presents the unadjusted and adjusted HRs for HIV viral suppression among CSBS participants newly diagnosed with HIV in NYC. The unadjusted HRs show that perceived neighborhood social cohesion was not associated with suppression. Persons who were black or Hispanic, born in the US or a US dependency, diagnosed in 2006-2009, or not eligible for treatment were at least 42% less likely to achieve viral suppression (range 42% to 60%) than others.

Multivariable regression included perceived neighborhood social cohesion, age at HIV diagnosis, sex at birth, race/ethnicity, year of HIV diagnosis, ART eligibility, and neighborhood-level poverty. Perceived neighborhood social cohesion was not associated with suppression in the fully adjusted model, nor were year of diagnosis or neighborhood-level poverty, which were among the potential confounders included. The likelihood of viral suppression was 55% lower for blacks or Hispanics (95%CI=0.23-0.86) than persons of another race/ethnicity, and 42% lower among persons not eligible for treatment (95%CI=0.35-0.96) than treatment-eligible persons, after adjustment. Compared with a model with variables for age at HIV diagnosis, sex at birth, race/ethnicity, year of HIV diagnosis, treatment eligibility, and neighborhood-level poverty, this model which added cohesion did not have significantly better fit (-2LL: 618.149; p=0.3372; see Appendix 10).

It is worth noting that these adjusted results for social cohesion remained similar when using a three-level rather than dichotomous variable (see Appendix 8).

Discussion

Controlling for individual characteristics and neighborhood poverty, perceived neighborhood social cohesion did not influence the time from HIV diagnosis to viral suppression. However, persons who were black or Hispanic and who were not eligible for treatment were less likely to achieve HIV viral suppression after diagnosis.

Our findings were not consistent with previous studies that have found a relationship between perceived neighborhood social cohesion and care-seeking behavior or STI outcomes.[44-46] Our study may have been underpowered to detect an effect of cohesion on suppression. However, it is also possible that cohesion is not associated with condom use, STIs, and care-seeking behaviors among persons with HIV in NYC, or that other factors may prevent social cohesion from influencing time to suppression. For example, the system of care and services, benefits, and large HIV-positive population in NYC make it a relatively attractive place for HIV-positive persons to live and receive care. These factors may affect the time to suppression regardless of neighborhood cohesion.

Findings about race/ethnicity and treatment eligibility were consistent with a previous study using NYC HIV surveillance data.[15] Treatment eligibility and suppression were associated with each other presumably because treatment-eligible persons were more likely to have been prescribed ART, almost

the exclusive means of lowering viral load. However, our findings on poverty were not consistent with previous studies; neighborhood-level socioeconomic factors have been associated with HIV diagnosis rates and some care-related outcomes in NYC and elsewhere.[31, 33, 38-42] Possible explanations for this inconsistency include: different outcomes (e.g., time from ART initiation to suppression vs. time from diagnosis to suppression); different settings (e.g., Canada vs. US, or other US areas vs. NYC); HIV care is perhaps comparably accessible and effective regardless of characteristics of the NYC neighborhood in which people live, mitigating neighborhood-level disadvantage after diagnosis; and publication bias may have limited the publication of previous null findings on neighborhood characteristics and HIV outcomes.[82, 83]

Limitations

As in any population-based analysis of HIV care, ours had VL data only when persons sought care, which was at their discretion. Persons in this analysis were not necessarily tested at regular intervals. Persons may have achieved suppression sometime before it was measured in a VL test. It is not clear whether these circumstances would have biased our hazard ratios. However, all persons in the analysis had at least one VL test between 8 days post-diagnosis and censoring. Persons diagnosed in 2009, for example, had a median of 13 VL tests (IQR: 7-17), and the median interval between tests was 140 days (<5 months; IQR: 106-264 days). Persons diagnosed in 2012 had a median of 8 tests (IQR: 6-10) and the median interval between tests was 85 days (<3 months; IQR: 67-98 days). These statistics indicate that the majority of New Yorkers recently diagnosed with HIV and interviewed by CSBS were engaged in care at intervals that were both consistent with federal guidelines and sufficiently frequent to produce estimates of suppression. Thus, it is unlikely that the lack of regular testing would have influenced our results.

Persons in this analysis were interviewed by CSBS, numbered fewer than 100 (n=92), and nearly universally achieved suppression by the end of the follow-up period. That these persons could be found in NYC and were sufficiently available for an interview suggests that they may differ from other recently diagnosed and reported New Yorkers, i.e., they may be more likely to still be living in NYC, be in care, and achieve suppression, although it is unclear whether this might affect the relationship between cohesion and suppression. Similarly, analyses of persons with HIV in NYC (who were not necessarily

recently diagnosed, unlike our analysis population) found that many reported to surveillance appeared to no longer live in NYC, and when those were excluded, the rates of care were higher.[14]

This analysis was conducted with a small population considering the numerous factors we sought to control for in multivariable analysis, and the study may have been underpowered. A post-hoc power calculation found that this study had only a 17% chance of rejecting the null hypothesis (i.e., no difference in suppression by perceived neighborhood social cohesion level).[107] It may also be that persons certainly in NYC (in this analysis, indicated by having been interviewed by CSBS) have high rates of suppression and that differences by subgroups are relatively small, offering an alternative explanation of why only a few characteristics were significantly associated with suppression. A previous study of newly diagnosed persons who, according to surveillance records, appeared never to have entered HIV care found that three times as many of these persons reported that they were in fact in care as the number who agreed that they were out of care.[108] With near-universal care engagement among persons completing CSBS interviews, subgroup differences in suppression may indeed be minor, supporting our findings that few factors measured by surveillance or the CSBS interview instrument were associated with suppression.

There are several steps between diagnosis and suppression in the continuum of care for HIV-positive persons.[10, 13] By design, this analysis did not elucidate the exact step(s) at which the factors measured affect suppression. This means that the associations that we found exist for the overall process from diagnosis to suppression but not necessarily for individual steps between them. For example, cohesion may not influence time from diagnosis to linkage of care but rather only time from linkage to suppression.

Strengths

This is the first analysis to investigate the influence of perceived neighborhood social cohesion on HIV outcomes, and among the first US analyses to use surveillance data to investigate the role of neighborhood factors on HIV outcomes. [31, 33, 35, 45, 46, 87] The data were drawn from the population-based HIV surveillance system of the city with largest HIV epidemic in the US, including only persons confirmed (by locating them at an NYC address) to still be in the jurisdiction. Data from multiple sources were used to assess the potential influence on viral suppression of factors beyond the individual. Mandatory electronic reporting of laboratory tests in NYC provided information about all measured VLs for

all HIV-positive persons receiving care in NYC, as opposed to in a clinical trials environment, where findings can differ from those in a population setting.

Conclusions

New Yorkers recently diagnosed with HIV, confirmed to be in NYC, and available for interview have almost universally achieved viral suppression. Being non-black or non-Hispanic and eligible for ART was associated with faster viral suppression after diagnosis, presumably leading to improved health and preventing ongoing HIV transmission. In contrast, individuals with characteristics associated with slower achievement of suppression may need more assistance after diagnosis with linkage to and retention in care or acquiring and adhering to ART. For example, black and Hispanic persons may benefit from more-frequent medical care and prescription of ART, including equitable prescribing behavior and/or better adherence support.[92] These changes may have the potential to raise suppression rates among blacks and Hispanics to levels that are comparable to those among whites.[15, 22, 25-27, 91] The racial/ethnic disparity in viral suppression was not related to estimated poverty status nor neighborhood poverty. Since 2010, New York State law has required all providers to link positive patients to care, and the United States Department of Health and Human Services now encourages antiretroviral therapy for all diagnosed persons, regardless of CD4 count, which should further the improvement in suppression rates. Future studies should explore the extent to which persons who can be located for a CSBS interview are representative of persons with HIV in NYC.

Chapter 5. Discussion

Overview

We measured the association of individual, facility, and neighborhood characteristics with the achievement and maintenance of HIV viral suppression among NYC residents diagnosed with HIV between 2006 and 2012. The dates of HIV diagnosis, viral suppression, and virologic failure were assessed using the NYC HIV surveillance registry, which included all persons diagnosed or receiving care in NYC as well as electronic reports of all of their subsequent viral load tests in NYC. Facility-level characteristics were obtained from the registry and based on facility of diagnosis or of first suppression. Finally, neighborhood-level characteristics were acquired from the US Census and American Community Survey based on Census tract or ZIP code of residence. The association of perceived neighborhood social cohesion with suppression was assessed for recently diagnosed New Yorkers interviewed by CSBS. For each analysis, the distribution of characteristics in the analytic population, the proportion achieving the outcome of interest within 12 months, and the median time to the outcome were presented. Kaplan-Meier curves were generated and log-rank tests performed to test for differences between subgroups in the likelihood of suppression. Then multivariable proportional hazards regressions were fitted to assess the likelihood of suppression or failure by individual, facility, and neighborhood characteristics, accounting for clustering of outcomes by facility or neighborhood whenever the sample size allowed it. Main findings and interpretations are reviewed in the following section.

Summary of findings

Chapter 2

This chapter assessed the association of individual, facility, and neighborhood factors associated with achievement of viral suppression after diagnosis among New Yorkers newly diagnosed with HIV in 2006-2010 (Aim 1). Of 12,547 New Yorkers newly diagnosed with HIV in 2006–2010, approximately three-quarters were 20-49 years old (78.7%), male (74.2%), and black or Hispanic (81.5%); and almost one-third were eligible to receive treatment based on CD4 and diagnosis year (30.6%). Forty-four percent of the population achieved suppression within 12 months of diagnosis, with a median time to suppression of 245 days. Suppression was achieved most slowly among persons who were younger,

diagnosed in earlier years, not known to be eligible for treatment, and diagnosed at non-hospital facilities and facilities farther from the patient's residence.

In proportional hazards models adjusting for individual and facility or neighborhood characteristics, we observed that persons 13-49 years old, men, blacks and Hispanics, US-born, heterosexuals, persons diagnosed in 2006 and 2008 were less likely to achieve suppression than those 60 and older, women, whites, foreign-born, MSM, and persons diagnosed in 2010, respectively. This was also observed for persons not eligible for treatment vs. treatment-eligible persons, and persons diagnosed at facilities that diagnosed 10-74 patients per year vs. facilities that diagnosed ≥75 patients per year, that were screening/diagnosis/referral sites vs. hospitals, or that were <1 mile from the patient vs. 1 to <5 miles. Neighborhood-level poverty, unemployment, and percent black residents were not associated with suppression.

Chapter 3

This chapter used the subset of persons from the previous aim's analytical sample who achieved viral suppression to assess the individual, facility, and neighborhood factors associated with maintenance of viral suppression (Aim 2). Of 8,927 New Yorkers newly diagnosed with HIV in 2006–2010 who achieved viral suppression, almost one-fifth (18.2%) experienced failure within 12 months of suppression with an overall median time to failure of 728 days, i.e., about two years after first suppression.

Adjusting for individual and facility or neighborhood characteristics, proportional hazards models show the following groups to be the least likely to maintain suppression: younger persons (<50 years old vs. ≥60), blacks and Hispanics, US- and US-dependency born persons, heterosexuals and injection drug users, persons with CD4 counts ≥500 cells/mL at suppression, persons receiving care at facilities that were not large outpatient facilities or large private practices, and residents of high- or very-high-poverty neighborhoods.

Chapter 4

This chapter assessed individual and neighborhood factors, particularly perceived neighborhood social cohesion, associated with achievement of viral suppression after diagnosis, among a sample of New Yorkers newly diagnosed with HIV in 2006-2012 (Aim 3). Out of 92 New Yorkers newly diagnosed with HIV in 2006–2012 and interviewed by CSBS, 65% achieved suppression within 12 months of diagnosis. Almost the entire population (95.7%) achieved viral suppression by the end of the follow-up

period on June 30, 2014, with a median of 180 days. Kaplan-Meier curves indicated no difference in time to suppression by perceived neighborhood social cohesion. In regression adjusting for age at HIV diagnosis, sex at birth, race/ethnicity, year of HIV diagnosis, ART eligibility, and neighborhood poverty, perceived neighborhood social cohesion was not associated with suppression.

Limitations

As in any population-based analyses of HIV care, ours had VL data only when persons sought care, which was at their discretion. Persons in our analyses were not necessarily tested at regular intervals. Thus, they may have achieved suppression or failure sometime before it was measured in a VL test. It is not clear whether these circumstances would have biased our hazard ratios. However, the majority of New Yorkers newly diagnosed with HIV between 2006 and 2012 were in fact engaged in care as frequently as was recommended by federal guidelines.

Persons not receiving care in NYC were presumed to be present and unsuppressed (in the analyses of time to suppression) or maintaining suppression for 12 months (in the analysis of time to failure), although they may have moved out of NYC and become suppressed or experienced failure elsewhere. Non-ascertainment of outmigration is a typical limitation of local HIV surveillance data and may be differential across subgroups. For example, if outmigration happened more frequently among men, which has been reported previously,[85] this could exacerbate the male-female disparity in suppression rates.

For the Aim 3 analysis, the analytical sample was fewer than 100 and with higher suppression rates than newly diagnosed persons citywide. We were underpowered to detect a difference in suppression between persons perceiving low vs. high neighborhood social cohesion. That these persons could be found and interviewed suggests that they may have higher rates of care than other newly diagnosed New Yorkers.[14] However, they may not necessarily have different predictors of suppression otherwise. A previous analysis of all NYC residents newly diagnosed with HIV found younger age and earlier year of diagnosis to be associated with delayed suppression.[15, 109] Alternatively, it may be that persons certainly in NYC (such as CSBS participants) have high rates of suppression and that differences between subgroups are relatively small.

There are several steps between diagnosis and suppression in the "care continuum" for HIV-positive persons.[10, 13] By design, our analyses did not elucidate the exact step(s) of the continuum – diagnosis, linkage to care, retention in care, provision of ART, or viral suppression – at which the characteristics studied affect suppression.

Strengths and public health significance

These are among the first analyses in the US to investigate the influence of facility and neighborhood, and the first to assess the influence of perceived neighborhood cohesion, on HIV outcomes using surveillance data,[31, 33, 35, 45, 46, 87] The data were drawn from population surveillance in a diverse city with the largest HIV epidemic in the US. Analyses combined data from multiple sources to assess the potential influence on the achievement and maintenance of viral suppression of factors beyond the individual. Mandatory electronic reporting of laboratory tests in NYC provided information about all measured VLs for all HIV-positive persons receiving care in NYC, as opposed to in a clinical trials environment, where findings can differ from those in a population setting. This makes our results generalizable to the population of NYC residents with HIV. To assign area-based characteristics to individuals, we used, whenever available, patient address geocoded to the Census tract, which is the gold standard for detection of public health disparities.[47] Aim 3 data included only persons confirmed (by locating them at an NYC address) to still be in the jurisdiction. This ensures that factors found to be associated with suppression are truly that, and not simply proxies for continued residence in NYC.

Policy recommendations and future research directions

We have identified individual, facility, and neighborhood characteristics that seem to help persons newly diagnosed with HIV to achieve and maintain viral suppression, and thus, improve their health and prevent ongoing HIV transmission. These individuals, health care facilities, or neighborhoods with characteristics associated with slower achievement of suppression may need more assistance with post-diagnosis linkage to and retention in care, ART prescribing, or adherence. Such supports might include care coordination, case management, behavioral counseling, strategic planning about the locations of facilities, or additional training for physicians. Below we describe the implications of our findings in each of these arenas in more detail as well as revisit the issue of study design and interviews of persons with

HIV. Our findings may be valuable to agencies planning testing programs, medical care for individuals with HIV, and "prevention with positives" programs. The agencies may wish to evaluate their effectiveness with these populations and/or expand their scope to reach most-affected groups or neighborhoods. Our findings may also help strengthen existing programs that appear to be working, such as the NYC care coordination program and housing services,[66, 67] or help explain why others may not work. For example, they may wish to place additional focus on individuals, facilities, or neighborhoods with characteristics associated with poorer achievement or maintenance of suppression; or review programs that help patients achieve relatively high rates of good outcomes in spite of challenges (i.e., serving persons who typically have poorer outcomes), as potential examples of best practices.

Individual characteristics

Several individual characteristics had previously been found to be associated with the achievement and maintenance of suppression,[15, 20, 21] and our adjusted analyses confirmed these associations. For example, persons who were older, white, foreign-born, diagnosed in later years, MSM, and eligible for ART were more likely to achieve and maintain suppression. Changing treatment guidelines favoring universal consideration of ART initiation will likely minimize the association of CD4 count (and somewhat, by extension, age) with suppression, but disparities by stage of illness and other factors, such as demographics, may remain. For example, black persons need better HIV-related care and/or support that permits them to receive optimal ART regimens and achieve and maintain suppression at comparable rates as whites;[15, 22, 25-27, 91] rectifying this disparity, which Chapter 4 suggested was related to individual race/ethnicity and not individual poverty status, neighborhood poverty, or neighborhood racial composition, may require more equitable prescribing behavior and/or better adherence support.[92]

Health care facility characteristics

We found a few associations between distance from a person's residence to their health care facility and achievement and maintenance of suppression. The extensiveness of NYC's systems of HIV care and public transportation,[97] coupled with New York State's generous benefits and services for

persons with HIV,[98] may have helped minimize the impact of patient-provider distance on virologic suppression failure.

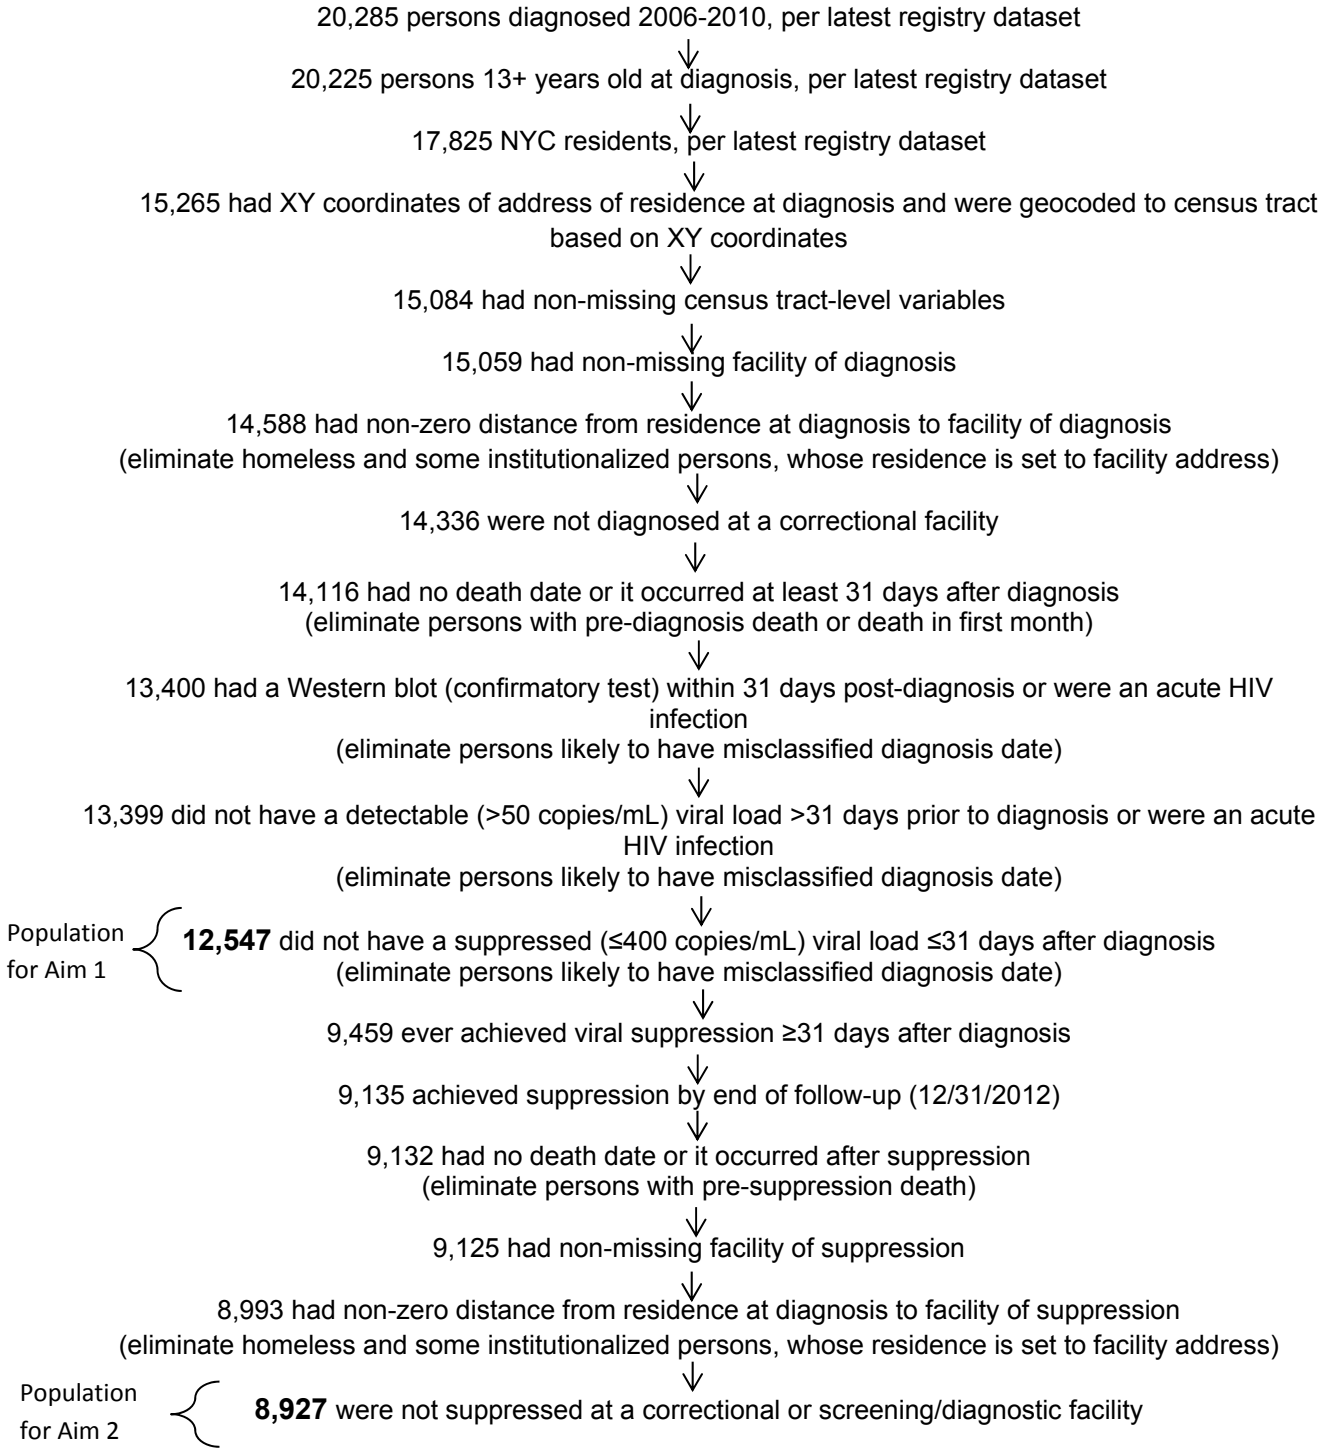
NYC can continue to encourage HIV testing at large facilities, including hospitals, where patients have the greatest likelihood of reaching suppression quickly. We can also increase the technical capacity of certain types of facilities, namely those that make fewer diagnoses annually, or that are neither hospitals nor private physicians' offices. These types of facilities need to do a better job at moving their patients along the continuum of care from diagnosis to suppression. An alternative solution may be ensuring effective linkage to care at a different type of site, such as one that has cared for more HIV-positive patients. Health care facilities where patients have better achievement and maintenance of suppression could be examined for their "best practices" and these practices considered either for scale-up across facilities or as recommendations of which types of facilities have the potential to provide the best care.

Several developments are encouraging all New Yorkers diagnosed with HIV to move along the continuum of care. Since 2010, New York State law has required all providers to link HIV-positive patients to care.[110] The United States Department of Health and Human Services now encourages antiretroviral therapy for all diagnosed persons, regardless of CD4 count.[3] Both sets of guidelines should further the improvement in suppression rates. Future studies should monitor whether facility-level disparities in suppression decrease over time, as more facilities presumably adhere to the law.

Neighborhood characteristics

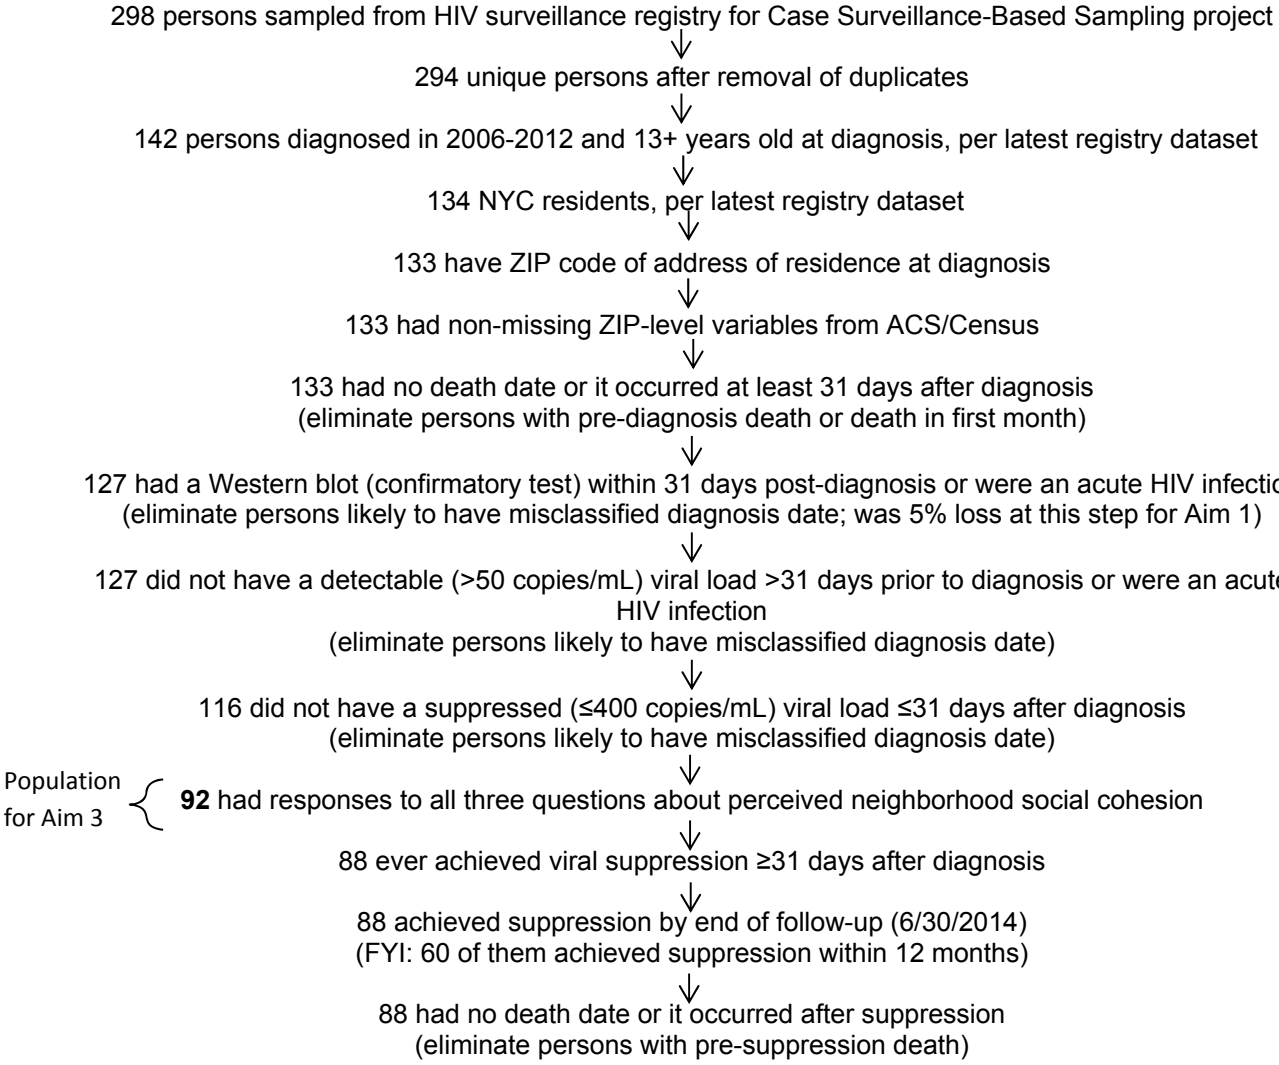
We found that neighborhood-level poverty influences maintenance of suppression but not achievement of suppression. This suggests that the many resources available for low-income PLWHA in NYC to receive care, medication, and other forms of support may reduce but not entirely eliminate the negative effects of poverty on HIV-related health outcomes. It is possible that the effects of neighborhood-level poverty would have been even larger in a setting other than NYC that may not have been as well-resourced vis-à-vis medical facilities and transportation system. Still, rectifying the disparity in maintenance of suppression between residents of poorer and wealthier neighborhoods may require

targeted adherence support services or additional general poverty alleviation, including increased units of subsidized and/or supportive housing.



Study design

We found near-universal care engagement and viral suppression among persons completing CSBS interviews, while figures among newly diagnosed PLWH overall were more modest. Future studies should explore the extent to which persons who can be located for an interview are representative of persons with HIV in NYC.



Conclusions

Our analyses are among the first in the US to reveal facility and neighborhood characteristics associated with achievement and maintenance of viral suppression among persons newly diagnosed with HIV. We confirm that several individual characteristics appear to also influence suppression, but perceived neighborhood social cohesion may not. We rely on population surveillance and interviews of persons sampled from surveillance, and matched both with US Census Bureau data to obtain information on neighborhood-level characteristics. Our results from Aims 1 and 2 are generalizable to the population of persons living with HIV in NYC, and further exploration of the representativeness of persons with HIV who can be located for an interview would be valuable. Increases in post-diagnosis linkage to and retention in care, and receipt of and adherence to ART, that reach groups of persons, patients at facilities, or residents of neighborhoods that we found to have poorer outcomes, may improve the achievement and maintenance of viral suppression in NYC.

Appendix 1. Populations for analyses of achievement (Aim 1) and maintenance (Aim 2) of HIV viral suppression among newly diagnosed New Yorkers

Appendix 2. Population for analysis of HIV viral suppression among recently diagnosed and interviewed New Yorkers (Aim 3)

Appendix 3. Creating a dataset of individual, neighborhood, and facility characteristics, January – May 2014

January 16 and 17, 2014 – Preparing individual-level dataset; reading in area-level variables

SAS

Added correctional variables, individual-level variables, first VL, first CD4, and provider XY coordinates. They are in a single completed SAS program and saved in a permanent SAS dataset called IndivSurvDataForGCCases_20140117. "GCCases" refers to geocoded cases.

Began a SAS program to read in and combine area-level datasets. Read in all ACS datasets and need to refer to Excel list at home of neighborhood-level variables, since some ACS datasets have hundreds of variables and the Excel list identifies the exact variable needed. Not all datasets have the same format for the geographic variables describing CT, so those will need to be made into the same format before merging.

Outcome

Finalized dataset with individual-level variables. Need to continue reading in and combining area-level variables. Have patient and provider XY coordinates and at some point need to do network analysis to calculate distance between them.

January 21, 2014 – Compiling area-level variables

SAS

Continued SAS program to read in and combine area-level datasets. Read in all needed CT-level ACS and Census data. Compared poverty datasets from ACS downloads done by borough and for NYC overall, and CT-level poverty stats between the two appeared to be a perfect match, which was reassuring. Converted all percentages into the same format (e.g., xx.x), since some were formatted as xx.x%, and formatted geographic info the same across datasets (as GEO_display_label in ACS was formatted) so they can be merged. Apparently there are 2,168 Census tracts in NYC with population data; this is the number of observations in the final area-level dataset.

January 23, 2014 – Creating permanent dataset of area-level variables

SAS

Finished program for CT-level data and saved permanent copy.

BES/DTF slides from approx. 1/16/2014 on combined/split CTs and ZIPs suggest that one ZIP perhaps should be combined with another.

January 28-30, 2014 – Creating facility-level variables, adding Aim 2 maintenance/failure variables, combining datasets across levels

SAS

Wrote code to determine number of cases diagnosed per provider per year (hars_name, hivdxdtafter year in hivepi.harsoct13sm for 2005-2010), number of unique patients seen per provider per year (hars_name, eventdate year of CD4/VL in care.vlcd4wbprovoct13 for 2005-2010), and facility type (provider and

providercode in hesp.pv_provider as of 1/30/2014, and DACs per NYS and NYC lists from 1/2006 – 2013). Saved datasets. Had to run on P because did it after 7pm when N was not available, then transferred datasets, SAS code, and DAC lists to N.

Revisited SAS program for individual-level data to add variables for Aim 2, e.g., 1st CD4 within 1 month before or after 1st suppressed VL, provider at 1st suppressed VL, and maintenance of suppression (i.e., failure per VL >400 or >1,000 or >366 days without a test).

Began SAS code to combine individual, neighborhood, and facility-level datasets.

January 31 and February 3-4, 2014 – Completing dataset for Aims 1 and 2, ruling out possibility of patient-provider XY distance network analysis

SAS

Checked the completeness of care patient load (FirstSuppVLProv by year of FirstSuppVLDate) and many were missing. Realized that the care patient load count by provider was only through 2010, so I reran that through the latest year of care data (2013) and recombined facility-level data with the individual-level dataset.

Reviewed provider XY coordinate availability and discovered that about one-third of patients that we'd want to have it (they were diagnosed in 2006-2010 and have a non-missing diagnosing provider) did not have provider XY coordinates. Looked at frequency of diagnosing providers (hars_name) with missing XY and found that numerous major providers (e.g., BELLEVUE, RIKERS ISLAND, BETH ISRAEL) had not been geocoded to XY coordinates. Network analysis does not seem possible without a major geocoding effort for providers.

Added dthdate (patient death date) to list of variables pulled from registry dataset, in order to calculate censor date.

Calculated censor dates, time from diagnosis or suppression to censoring, and whether censoring was due to the outcome of interest (suppression for Aim 1, failure for Aim 2). Censoring variables for Aim 2 are available at VL>400 and VL>1,000.

Completed SAS code to combine individual, neighborhood, and facility-level datasets.

February 5, 2014 – Reviewing variables and population, and adding hboro

SAS

Read in combined indiv/neighb/facility dataset and reviewed most variables with freqs and measures of central tendency. All (individual and neighborhood) look okay so far – need to check provider and outcome variables still.

Added hboro to datasets, to be able to specify the population as persons living in NYC at diagnosed.

April 15, 2014 – Expanding provider characteristics

SAS

Created SAS program to calculate two measures of patient volume: annual diagnoses by provider (for use in aim 1 for facility of diagnosis) and unique patients cared for by provider (for use in aim 2 for facility of first viral suppression), as well as facility type (for aims 1 and 2).

April 17, 2014 – Revising neighborhood variables

SAS

Created additional variable of percent of population that did not graduate from high school for greater consistency with the literature. Previously we had variables for percent finishing high school and percent finishing college. Percent not graduating from high school was calculated as 100 - percent graduating from high school.

Also divided all neighborhood variables by 10 so that, when modelled as continuous variables, the resulting measure of association would represent the hazard ratio for each 10-percentage-point increase in the variable. For example, the percent not graduating high school was 60, but the percent not graduating high school divided by 10 was 6, and the latter variable was modelled, so the hazard ratio for each 1-point change in the latter variable represented a 10-percentage-point change.

May 20, 2014 – Excluding persons with possibly misclassified diagnosis date

SAS

Several edits were made between February 5 and May 21 but not documented here, including the reincorporation of provider XY data since many more had it after a March/April geocoding by Keyi Xu.

On May 20, three exclusions were added to bring the population closely in line with that in Lucia Torian and Qiang Xia's paper on viral suppression among newly diagnosed New Yorkers, which sought to remove persons whose diagnosis dates may have been misclassified. These three exclusions were:

1. Persons who did not have a Western blot within 31 days of diagnosis and were not acute HIV infections
2. Persons who had a detectable (>50 copies/mL) viral load >31 days prior to HIV diagnosis
3. Persons who had a suppressed (>400 copies/mL) viral load ≤31 days following HIV diagnosis

This resulted in a reduction in our analysis population from 14,065 cases to 12,547 cases. Proportion suppressed decreased from 73.8 to 72.8% and median time to suppression increased from 225 to 245 days.

Appendix 4. Calculating shortest distance along NYC streets from patient residence at diagnosis to facility of diagnosis using Network Analyst in ArcGIS

Created XY datasets. We created a single dataset that included variables for patient identifier (cityno), XY coordinates for patient residence at HIV diagnosis, and XY coordinates of the facility that diagnosed HIV in each patient. We transferred this dataset from the most-secure drive to a less-secure drive that has ArcGIS on it. We split this dataset into two, each with the patient identifier and each one having either patient or provider XY coordinates. We copied cityno in each XY Excel file into a second column in each called RouteName. We ensured that patient and provider XY were numeric. We also deleted provider records with missing XY. We named the files "ptxy20140313" and "provxy20140313."

Got Network Analyst. We opened ArcMap and in the Customize menu, selected Extensions – Network Analyst, then closed the window. Then in the Customize menu again, we selected Toolbars – Network Analyst to get the toolbar for this extension.

Obtained network dataset. We obtained the "MP_Network" network dataset of NYC streets. This network dataset is a simple network of NYC streets without details that for our purposes would be extraneous, like which streets are one-way, as we are not interested in actual driving directions. We used Add Data to add MP_Network and specifically NYC_Streets within it, and said "Yes" to also add to the map all feature classes that participate in the network dataset. The Network Analyst toolbar now had in its "Network dataset" window "NYC_Streets_ND." Three layers showed up from this in the Table of Contents: lines, dots for junctions, and lines for edges.

Added XY data to map. We clicked Add Data and added ptxy20140313 and provxy20140313 data from Excel, right-clicked on each to display XY data, and clicked Yes to add the data to the map as a layer (ptxy Events and provxy Events).

Exported XY data to file geodatabase of network dataset. XY data are most easily routed in Network Analyst when saved within the file geodatabase of the network dataset. With the ptxy Events layer, we right clicked, exported data, navigated to the MP_Network geodatabase folder, selected the geodatabase within that, named ptxy as a personal gdb/features class, closed, clicked Yes to add to map as layer, and deleted the original Events layer from the Table of Contents. We did the same with the provxy Events layer. Right-clicked on each to display XY data, and clicked Yes to add to the map as a layer.

Established settings for routing. In the Network Analyst toolbar, clicked the arrow next to "Network Analyst" and selected New Route. In the Table of Contents, immediately under the NYC_Streets layer, we right-clicked on Route → Properties → Analysis settings → Output shape type → Straight line. Routing as a straight line doesn't affect the distance being calculated but may help the routing run faster in ArcMap.

Loaded XY coordinates into Network Analyst. In the Network Analyst window, we right-clicked the Stops line and (after acknowledging with No that we didn't want to repair the address locator) clicked Load Locations, then selected ptxy (the only one with that name in the Table of Contents), selected sorting by Routename, and checked that the Routename property was affiliated with the Routename field in our origins (patient) table. We clicked OK, and this ran in about five minutes We right-clicked Stops,

Load Locations, selected provxy, selected sorting by Routename, and confirmed Routename was affiliated with Routename field in table, clicked OK, and let ArcMap run for another five minutes.

Calculated and reviewed distances. We clicked the Solve icon (a small square with gridlines and a blue line) in the Network Analyst toolbar and let it run for 15-30 minutes this time. This calculated the distances between each person's residence and facility of diagnosis, as well as created straight-line "routes" from each patient to his/her facility of diagnosis. We displayed these on the map, added ZIP and borough shapefiles for context, and exported this map as a PNG image file, not for publication (XY patient locations are confidential) but for internal visual review. We noted that nearly all of Manhattan was completely blanketed by routes, and most of the other boroughs were also largely covered.

Saved dataset of distances. In the Network Analyst window, we right-clicked Routes → Data → Export data → Use the same coordinate system as the data frame → Named it "PtProvDistance" and saved in the main (non-geodatabase) folder, and said Yes to add exported data to map as a layer. Then in Windows Explorer, we opened the DBF that was just created that was affiliated with the shapefile, gave it another name and saved as Excel, kept only cityno and total length (shape length, which was slightly shorter, is the length of the straight-line route drawn between each patient's residence and facility of diagnosis), and created new columns calculating equivalent miles and kilometers from the distance in feet.

Removed data from less-secure drive. We deleted or transferred back to the most-secure drive all files on the less-secure drive related to the calculation of patient-provider distance.

We found the following online resources helpful:

ArcGis Network Analyst tutorial at http://help.arcgis.com/en/arcgisdesktop/10.0/pdf/network-analyst-tutorial.pdf

Post #3 in online forum at http://forums.arcgis.com/threads/30795-calculating-driving-distances

We would like to acknowledge the following persons for their help with network analysis:

Susan Resnick, NYC DOHMH DIIT, for providing network dataset and help with Network Analyst

Andrew Maroko, Lehman College, CUNY, for providing help with Network Analyst, including remotely walking us through the actual routing

Appendix 5. Assessing model fit for Aim 1

An Excel table was made indicating the set of variables in each proportional hazards regression model. The -2LL (with covariates) was recorded from SAS for each model. The difference in -2LL and degrees of freedom were entered into a X^2 calculator at https://www.fourmilab.ch/rpkp/experiments/analysis/chiCalc.html on February 4, 2015. We used the "Calculate probability from X^2 and d" section of the webpage and manually copied each difference in -2LL, out to three significant digits, into the "Given X^2=" box, entered each number of degrees of freedom into the "d=" box, and clicked "Calculate" to get a value in the "The chance probability, Q, is:" box. For example, the model of time from diagnosis to viral suppression that had all three neighborhood-level variables in addition to the seven individual-level variables had a -2LL of about 158,673, whereas the individual-only model's -2LL was about 158,675, for a difference of 2.190 with three degrees of freedom (see Table A5.1). The calculator indicated that the probability of getting a difference at least as large with these degrees of freedom was 0.5339, meaning that the addition of the three neighborhood-level variables did not statistically significantly improve the fit of the model over individual-level variables alone. The model of suppression that had the best fit was that with all individual- and facility-level variables, which had a -2LL of 158,585 (p<0.0001).

Table A5.1. Measures of the fit of proportional hazards models of HIV viral suppression among persons newly diagnosed with HIV in New York City in 2006-2010 and followed through 2012, by individual, facility, and neighborhood characteristics

Variable	Variable type	Model 1	Model 2	Model 3	Model 4	Model 5	Model 6	Model 7	Model 8	Model 9
Age group (years) at diagnosis	Individual	x	x	x	x	x	x	x	x	x
Sex at birth	Individual	x	x	x	x	x	x	x	x	x
Race/Ethnicity	Individual	x	x	x	x	x	x	x	x	x
Country of birth	Individual	x	x	x	x	x	x	x	x	x
HIV transmission risk	Individual	x	x	x	x	x	x	x	x	x

Year of HIV diagnosis	Individual	x	x	x	x	x	x	x	x	x
Eligible for treatment	Individual	x	x	x	x	x	x	x	x	x
Number of HIV diagnoses made annually by health care facility that diagnosed patient	Facility		x		x					
Type of facility that diagnosed patient	Facility		x			x				
Distance between patient and provider	Facility		x				x			
Percent of population below federal poverty threshold in past 12 months	Neighborhood			x				x		
Unemployment rate among population 16 years and over	Neighborhood			x					x	
Percent of population that is black or African American only (non-Hispanic)	Neighborhood			x						x
Measure of fit: -2LL ("with covariates")		158,675	158,585	158,673	158,642	158,626	158,663	158,673	158,675	158,675
Comparison with model with all individual-level variables, using X^2										
Difference in -2LL		N/A	90.080	2.190	33.230	48.860	11.350	2.070	0.040	0.040
Degrees of freedom		0	3	3	1	1	1	1	1	1
p-value		N/A	<0.0001	0.5339	<0.0001	<0.0001	0.0007	0.1502	0.8414	0.8414

Appendix 6. Patterns of viral load testing

Of 12,547 persons in our analytic sample for Aim 1, i.e., persons newly diagnosed with HIV in 2006-2010 whose address at diagnosis geocoded to an NYC Census tract, 1,446 (11.52%) had no viral load (VL) test between 8 days post-diagnosis and their censor date. Thus, 88.5% (n=11,101) of persons in the analysis had at least one VL test ≥8 days after diagnosis (ranging only narrowly by diagnosis year: 87-90% each year).

Among this group of 11,101 persons, there were a median of 12 (IQR: 7-17) VL tests during follow-up (median of 17 [IQR: 10-23] among those diagnosed in 2006 and median of 8 [IQR: 5-10] among those diagnosed in 2010, for whom follow-up time was shorter), with a median interval of 112 (IQR: 90-164) days (i.e., 3-4 months) between tests (median of 120 days [IQR: 95-182] among those diagnosed in 2006 and median of 101 [IQR: 84-139] among those diagnosed in 2010). Out of the 11,101 persons with at least one VL test ≥8 days after diagnosis, 19% had their first VL test within 14 days of diagnosis (i.e., 8-14 days), 45% within 30 days, 67% within 60 days, 76% within 91 days, 87% within 183 days, 90% within 274 days, and 92% within 365 days.

Appendix 7. Young teenagers, facility type and patient volume, changes in residence over time, and model fit for Aim 2

A7.1. Young teenagers

The discussion argues that information about teenagers is unique because they are rarely included in analyses of viral suppression before 18 years of age. To support this statement, I checked the number of persons in the analysis for Aim 2 who were aged 13-17 years at their first viral suppression after diagnosis. I compared this number with the number of persons 18-19 years old at suppression and calculated the proportion of persons 13-19 years old (i.e., teenagers, one of the age groups in the analysis) who were 13-17. I found that 55 of the teenagers were 13-17 years old, and 141 were 18-19 years old (Table A7.1). Thus, 13-17-year-olds comprised a non-negligible number of persons, and 28% of teenagers, in the analysis. Based on this information, we will keep our argument about teenagers in the Discussion. As an additional note, only 7 of the 13-17-year-olds were 13-15 years old; 48 were 16-17.

Table A7.1. Number of teenagers in analysis, by age group

Age group at first viral suppression	Number of teenagers in analysis	Percentage of teenagers in analysis (%)
13-17*	55	28
*13-15**	*7*	*4*
*16-17**	*48*	*24*
18-19	141	72
Total teenagers (13-19 years old)	**196**	**100**

*These age groups are rarely presented in other analyses of viral suppression.

A7.2. Facility type and patient volume

We found that persons receiving care at facilities with small patient volumes had higher failure rates than those at facilities with larger patient volumes, and that persons receiving care at facilities that were not private physicians' offices had higher failure rates than patients of private physicians, after controlling for individual and other facility or neighborhood characteristics. To prevent confusion in the interpretation of these findings, it would be helpful to know if facility type and patient volume were correlated, e.g., private physicians' offices had smaller patient volumes. To address this issue, I cross-tabulated facility type and patient volume among all 8,927 persons in the Aim 2 analysis population and

conducted a Chi-squared test of association. This analysis shows that, for most persons who were first suppressed at private physicians' offices (850/1,564, 54%), their facilities saw fewer than 1,000 patients for HIV-related medical care that year, whereas for most persons who were first suppressed at an inpatient facility or hospital, their facilities saw at least 1,000 patients (3,865/4,879, 79%; Table A7.2). The Chi-squared test indicated a statistically significant association between facility type and patient volume (p<0.0001). However, facility type and patient volume were not equivalent: most persons who first suppressed at facilities with patient volumes of <250 were *not* at private physicians' offices. The paper was revised so that the proportional hazards models use the combined variable rather than facility type and patient volume separately.

Table A7.2. Number of persons first suppressed at each facility type, by patient volume

Unique patients seen for care (CD4 or VL) at facility of first suppression in year of first suppression		Facility type									
		Inpatient / Hospital		Outpatient: Non-private		Outpatient: Private		Other / Unknown		*Total*	
		N	Col. %	N	Col. %	N	Col. %	N	Col. %	*N*	Col. %
<250		116	2	884	38	850	54	101	54	*1,951*	22
250 to <1,000		898	18	676	29	608	39	85	46	*2,267*	25
1,000 to <2,000		2,020	41	216	9	106	7	0	0	*2,342*	26
>=2,000		1,845	38	522	23	0	0	0	0	*2,367*	27
Total	*N*	*4,879*	100	*2,298*	100	*1,564*	100	*186*	100	*8,927*	100
Total %	*Row %*	*55*		*26*		*18*		*2*		*100*	

A7.3. Changes in residence over time

Residence information from the time of HIV diagnosis was used to provide neighborhood-level data for persons in the analysis. Address of residence was geocoded to the Census tract, which was then used to assign neighborhood poverty level, percent black, and percent unemployed. Complete and accurate geocoding is labor-intensive, so we did not attempt to determine or geocode address at the time of first suppression. Rather, we assumed that the characteristics of a person's Census tract of residence at first suppression were the same as those at diagnosis. To better understand how this might affect the internal validity of our results, we assessed moves among NYC residents 13+ who were diagnosed in

2006-2010 and would go on to achieve suppression ≥31 days after diagnosis and by the end of the follow-up period (12/31/2012). In the October 2013 analytic dataset, this included 12,584 persons, quite a bit more than the dissertation Aim 2 analysis population of 8,927. This may be because of the loss in the dissertation analysis of persons whose address at residence did not geocode, plus other exclusion criteria, which could not readily be included for this appendix analysis.

Among these 12,584 persons, we compared the United Hospital Fund (UHF) neighborhood, borough, and ZIP-level poverty level of their residence at diagnosis with their UHF neighborhood, borough, or ZIP-level poverty level, respectively, as of the end of (a) their diagnosis year and (b) the next calendar year. For example, for someone diagnosed anytime in 2007, we assessed whether the UHF at diagnosis was the same as the UHF as of the end of 2007 and the end of 2008, whether the borough at diagnosis was the same as the borough as of the end of 2007 and the end of 2008, and whether the poverty level of their ZIP code at diagnosis was the same as that of their ZIP code as of the end of 2007 and the end of 2008. We chose these measures because they were readily available and because 44% of persons in the main dissertation analysis for Aim 1 achieved viral suppression within 12 months of diagnosis. The proportion of persons who would have moved by the time they achieved suppression may be estimated by the midpoint of the proportion of persons who moved by the end of *diagnosis year* (for whom median time elapsed would be six months) and the proportion of persons who moved by the end of the *year after diagnosis* (for whom median time elapsed would be 18 months). Residence information in surveillance is updated largely based on laboratory test values; persons achieving suppression by definition would have had laboratory test values subsequent to diagnosis (although not necessarily within one calendar year after diagnosis).

We assessed change in residence overall and by diagnosis year. We found no large differences by diagnosis year in moves across UHFs, boroughs, or poverty levels, so Table A7.3 (below) presents statistics on changes in residence aggregated across diagnosis years. Overall, 16% of persons had changed *UHFs* by the end of their diagnosis year and 27% by the end of the calendar year following their diagnosis, 7% had changed *boroughs* by the end of their diagnosis year and 13% by the end of the calendar year following their diagnosis, and 12% had changed *poverty levels* by the end of their diagnosis

year and 21% by the end of the calendar year following their diagnosis. Midpoints were 21% changing UHF, 10% changing borough, and 16% changing poverty level.

UHFs are larger than Census tracts, suggesting that more than 21% of persons in our analysis may have changed Census tract of residence between diagnosis and suppression. The cross-borough figures are more modest, but those and, to a greater extent, the cross-poverty figures suggest that many persons moved to places substantially different from those they were living in at diagnosis. Similarly, in the dissertation Aim 2 analysis, many persons may have moved by the time they achieved suppression to Census tracts with different characteristics, e.g., poverty level, than the Census tracts they were living in at diagnosis. Additionally, the rate of moving itself (>21%) suggests that the impact of neighborhoods on the achievement of viral suppression may be difficult to measure, as many persons live in more than one neighborhood between diagnosis and suppression, albeit sometimes similar neighborhoods. Our longitudinal analysis, which uses information about residence at one time point only (and moreover, one that falls before the baseline), is somewhat limited in its ability to assess the role of neighborhood on participant outcomes.

Table A7.3. Change in residence among New York City (NYC) residents who were newly diagnosed with HIV in 2006-2010 and achieved viral suppression by the end of 2012

	Timing of the change		
Geographic level	**By end of diagnosis year (%)**	**By end of year after diagnosis (%)**	***Midpoint (%)***
Moved to different UHF neighborhood	16	27	*21*
Moved to different NYC borough	7	13	*10*
Moved to ZIP code with different poverty level	12	21	*16*

*For persons diagnosed in 2007-2010 only, because information about residence at the end of 2006 was not available.

A7.4. Model fit for Aim 2

Table A7.4. Measures of the fit of proportional hazards models of HIV virologic failure after suppression among persons newly diagnosed with HIV in New York City in 2006-2010 and followed through 2012, by individual, facility, and neighborhood characteristics

Appendix 8. Clarifying and exploring the Aim 3-specific variable of perceived neighborhood social cohesion

A8.1. How the Aim 3-specific variable of perceived neighborhood social cohesion was created

Perceived neighborhood social cohesion was calculated based on the degree of participant agreement with three statements in the Case Surveillance-Based Sampling (CSBS) interview about trust, closeness, and helpfulness between neighbors. [45, 46] These statements were:

a. I live in a close-knit neighborhood.

b. People in my neighborhood can be trusted

c. People in my neighborhood are willing to help each other.

Agreement with each statement were collected using a scored 1-4 Likert scale: strongly agree (1), agree (2), disagree (3), and strongly disagree (4). Scores for the three responses were summed, and these sums of 3-12 were dichotomized near the median, at a natural break that would place approximately equivalent numbers of persons in each category.[46] Specifically, the majority of sums were 6, 9, or 12 (>20% each), and 48% of persons had sums of 3-8 (see Table A8.1). Lower scores indicated agreement with positive statements about the neighborhood; perceived neighborhood social cohesion was classified as high for persons with sums of 3-8 (48% of the sample population) and low for persons with sums of 9-12 (52% of the sample population; see Table A8.2).

Table A8.1. Sums of responses to three cohesion-related questions in Case Surveillance-Based Sampling interview, among 92 persons in analysis of viral suppression among newly diagnosed New York City residents

cohesionOrig: Sum of three cohesion variables				
cohesionOrig	**Frequency**	**Percent**	**Cumulative Frequency**	**Cumulative Percent**
3	2	2.17	2	2.17
5	3	3.26	5	5.43
6	22	23.91	27	29.35
7	8	8.70	35	38.04

cohesionOrig: Sum of three cohesion variables				
cohesionOrig	Frequency	Percent	Cumulative Frequency	Cumulative Percent
8	9	9.78	44	47.83
9	22	23.91	66	71.74
10	3	3.26	69	75.00
11	4	4.35	73	79.35
12	19	20.65	92	100.00

Table A8.2. Dichotomized cohesion measure based on responses to three cohesion-related questions in Case Surveillance-Based Sampling interview, among 92 persons in analysis of viral suppression among newly diagnosed New York City residents

LowCohesion: Poor neighborhood social cohesion (cohesionOrig score is high: 9-12)				
LowCohesion	Frequency	Percent	Cumulative Frequency	Cumulative Percent
0	44	47.83	44	47.83
1	48	52.17	92	100.00

A8.2 Cohesion as a three-level variable

Perceived neighborhood social cohesion could have been categorized in a way that reflected the distribution of values differently. Because most persons in our sample had cohesion scores of exactly 6, 9, or 12, we constructed an alternative version of the cohesion variable with three levels rather than two. For this, cohesion was classified as low if the sum of the three cohesion variables was 10-12, medium if 7-9, and high if 3-6. Approximately equal proportions of the sample population were in each group.

We ran a multivariable proportional hazards regression with this alternative version of the cohesion variable (see Table A8.3). As with the original version of the variable, we found that increasing levels of cohesion were associated with reduced hazards of suppression, and that this association was still not statistically significant.

Table A8.3. Proportional hazards regressions of HIV viral suppression among a stratified random sample of persons newly diagnosed with HIV in New York City in 2006-2012 who were interviewed and followed through June 2014, including perceived neighborhood social cohesion as a three-level variable

	AHR[1] (95% CI)
Perceived neighborhood social cohesion	
Low cohesion	1.00
Medium cohesion	0.73 (0.42-1.28)
High cohesion	0.69 (0.34-1.43)
Age group (years) at diagnosis	
13 - 29	0.62 (0.35-1.08)
≥30	1.00
Sex at birth	
Male	0.93 (0.53-1.61)
Female	1.00
Race/Ethnicity	
Black or Hispanic	0.43 (0.21-0.85)
Another race/ethnicity	1.00
Year of HIV diagnosis	
2009 - 2009	0.60 (0.35-1.03)
2010 - 2012	1.00
Eligible for treatment	
Yes	1.00
No	0.60 (0.36-0.99)
Percent of population below federal poverty threshold in past 12 months	
Low or medium (<20%)	1.00
High or very high (≥20%)	1.00 (0.98-1.03)

[1] AHR: Adjusted hazard ratio

Appendix 9. The creation of the Aim 3-specific variable for individual-level poverty, i.e., estimated poverty status

Aim 3 was limited to persons interviewed by the Case Surveillance-Based Sampling project, which, unlike routine HIV surveillance in NYC, asked participants' household size and income. This provided a unique opportunity to assess poverty at the household/individual level. (Both CSBS and routine HIV surveillance collect information about the place of residence of New Yorkers with HIV and can use residence data in combination with US Census Bureau data to assess neighborhood-level poverty.) In short, we combined US Census statistics on poverty thresholds by family size with self-reported household income from CSBS and number of persons who depended on the income (which we treated as a proxy for family size), to create a variable dichotomizing each person as poor or non-poor. We called this measure "Estimated poverty status," and this appendix provides more details about its creation.

The relevant CSBS variables to create this poverty measure are described in the CSBS protocol's Appendix D1, "2012/2013 Case-Surveillance-Based-Sampling Questionnaire for The Medical Monitoring Project (MMP)" (see Figure A9.1). Monthly or yearly income was collected only as a range of values, not a specific dollar amount.

Figure A9.1. Questionnaire extract for income-related questions

SAY: "Please take a look at **Response Card A** and tell me the letter that corresponds to either your monthly or yearly household income before taxes."

Monthly Income *[MTH_IN12]*		**Yearly Income** *[YR_IN12]*	
a.	$0 to $416	j.	$0 to $4,999
b.	$417 to $833	k.	$5,000 to $9,999
c.	$834 to $1249	l.	$10,000 to $14,999
d.	$1250 to $1666	m.	$15,000 to $19,999
e.	$1667 to $2499	n.	$20,000 to $29,999
f.	$2500 to $3333	o.	$30,000 to $39,999
g.	$3334 to $4166	p.	$40,000 to $49,999
h.	$4167 to $6249	q.	$50,000 to $74,999
i.	$6250 or more	r.	$75,000 or more
77	Refused to answer	77	Refused to answer
88	Don't know	88	Don't know

D14a. Including you, how many people depended on this income in **2011** (2012)? *[DEPND_IN]*

___ ___ *[77 = Refused to answer, 88 = Don't know]*

CSBS participants were asked to use a response card to indicate either their monthly or yearly income (see Figure A9.2).

Figure A9.2. Participant response card for monthly and yearly income questions

RESPONSE CARD A

	Monthly Income		Yearly Income
a.	$0 to $416	j.	$0 to $4,999
b.	$417 to $833	k.	$5,000 to $9,999
c.	$834 to $1249	l.	$10,000 to $14,999
d.	$1250 to $1666	m.	$15,000 to $19,999
e.	$1667 to $2499	n.	$20,000 to $29,999
f.	$2500 to $3333	o.	$30,000 to $39,999
g.	$3334 to $4166	p.	$40,000 to $49,999
h.	$4167 to $6249	q.	$50,000 to $74,999
i.	$6250 or more	r.	$75,000 or more

Variables for monthly and yearly income had corresponding values, such that the lowest category of monthly income response would be equivalent to the lowest category of yearly income response, were that monthly income earned for 12 months (see Table A9.1). For example, persons in households earning up to $4,999 in a year would earn $4,999/12 = $416/month, and either response was coded as a "1."

Table A9.1. Codebook of CSBS participant responses for monthly and yearly income and number of persons depending on the income

MTH_IN12	8	Monthly combined household income^[MTH_IN12]	1	(1)a. $0 to $416

			.S	(S)Skipped
			.	Missing

Because monthly and yearly income variables were coded in parallel fashion, because participants typically responded to only one of those variables, and to be conservative about who was counted as poor, we created a variable for income category that took the larger value of either monthly or yearly income.

We obtained a table of US poverty cutoffs from the Census Bureau based on family size (see Table A9.2).

Table A9.2. Poverty Thresholds for 2013 by Size of Family and Number of Related Children Under 18 Years

Size of family unit	Weighted average thresholds	Related children under 18 years								
		None	One	Two	Three	Four	Five	Six	Seven	Eight or more
One person (unrelated individual).....	11,888									
Under 65 years.....	12,119	12,119								
65 years and over.....	11,173	11,173								
Two people.....	15,142									
Householder under 65 years.....	15,679	15,600	16,057							
Householder 65 years and over.....	14,095	14,081	15,996							
Three people.....	18,552	18,222	18,751	18,769						
Four people.....	23,834	24,028	24,421	23,624	23,707					
Five people.....	28,265	28,977	29,398	28,498	27,801	27,376				
Six people.....	31,925	33,329	33,461	32,771	32,110	31,128	30,545			
Seven people.....	36,384	38,349	38,588	37,763	37,187	36,115	34,865	33,493		
Eight people.....	40,484	42,890	43,269	42,490	41,807	40,839	39,610	38,331	38,006	
Nine people or more.....	48,065	51,594	51,844	51,154	50,575	49,625	48,317	47,134	46,842	45,037

Source: U.S. Census Bureau.

We used the weighted average thresholds from this table as income cutoffs. However, these did not correspond perfectly with CSBS income categories. We created an approximate crosswalk of Census thresholds and CSBS yearly household income (see Table A9.3). Persons with a CSBS income category that was at or below the cutoff category were classified as poor. We again erred on the side of being conservative, i.e., not classifying a family as poor if most of the values in an income range were above the poverty threshold for that family size. For example, for one-person families, the poverty threshold was $11,888, and we linked this with CSBS income category 2. This meant that any CSBS participant reporting CSBS income categories 1 or 2 (i.e., yearly income below $9,999) and stating that only one person was dependent on this income would be classified as poor. CSBS participants reporting CSBS income category 3 (i.e., yearly income of $10,000-$14,999) with one person dependent on this income would be classified as non-poor, even though some of those persons may have had incomes between $10,000 and $11,888.

Table A9.3. Approximate crosswalk of Census poverty thresholds and CSBS yearly household income, by family size

Size of family unit	Weighted average thresholds (dollars)	Highest CSBS income category beneath the threshold (approx)
1	11,888	2
2	15,142	3
3	18,552	4
4	23,834	4
5	28,265	5

6	31,925	5
7	36,384	6
8	40,484	6
9	48,065	7

This process permitted us to assign an estimated poverty status, i.e., an individual-level poverty measure, to each CSBS participant who answered interview questions about monthly or yearly household income and number of persons who depended on this income. Persons missing any of this information were excluded from our analyses.

Table A10.1. Measures of the fit of proportional hazards models of HIV viral suppression among a stratified random sample of persons newly diagnosed with HIV in New York City in 2006-2012 who were interviewed and followed through June 2014, by individual and neighborhood characteristics

Autobiographical Statement

is an epidemiologist specializing in infectious diseases and health disparities. She has over 12 years of experience in the field of HIV surveillance and epidemiology and has worked at the New York City Department of Health and Mental Hygiene since 2003. Areas of focus include HIV-related care outcomes; social determinants of health; poverty and housing; and populations marginalized along the lines of race or ethnicity, nationality or origin, and gender identity.

She holds a Master of Health Science degree in infectious disease epidemiology from the Johns Hopkins Bloomberg School of Public Health and a Bachelor of Arts degree in biology and sociology from Smith College.

Investigation of the Effects of Graphic Cigarette Warning Labels on Youth and Adult Smoking Behavior in Southeast Asia

Abstract

Investigation of the Effects of Graphic Cigarette Warning Labels on Youth and Adult Smoking Behavior in Southeast Asia by

Adviser: Professor William T. Gallo, PhD

The objective of this dissertation was to investigate the impact of graphic cigarette warning label policies enacted in Thailand and Malaysia on youth and adult smoking outcomes. We sought to examine the effect of the policy on youth smoking intention, susceptibility, and behaviors. Among adults, who were all baseline smokers, we sought to examine the effects of graphic warning labels on smoking intensity, quit attempts, and cessation. Secondary data were utilized from the International Tobacco Control (ITC) South East Asia (SEA) Survey, a nationally representative cohort survey for which eight years of data spanning from 2005 to 2012 were available. Multiple wave-pairs of data were analyzed concurrently using generalized estimating equations (GEEs) with the predictors measured at a baseline wave (wave t) predicting outcomes measured at the next wave, the outcome wave (wave t + 1). Thus, it was possible for participants to provide data for multiple wave-pairs which increased the power of the study.

We analyzed our data using two approaches. In our first approach, we utilized a quasi-experimental design capturing the time period after which Thailand had enacted the policy, but prior to policy implementation in Malaysia. Using this approach, outcomes were assessed for our Thai sample using the Malaysian sample as a control, whereby country differences reflected the effects of the graphic warning label policy. In our second approach, we limited the data to the post-policy implementation period in both countries to assess the effect of frequency of exposure to graphic warning labels on smoking outcomes among youth and adults. We employed measures of risk cognition and label salience as proxies for frequency of exposure, due to the potential collinearity between smoking status and exposure to warning labels which may have contaminated our analyses of smoking outcomes.

This study found that graphic cigarette warning labels significantly reduced future smoking intention among Thai male youth smokers, as well as increased the odds of intending to quit smoking within 6 months. Among female never-smokers, the policy decreased intention to smoke. We also found high cognition of risk to be significantly associated with decreased susceptibility to smoking, decreased odds of smoking initiation, and reduced smoking intensity among male youth.

Among adult smokers, our findings indicate that *any* label salience was associated with increased odds of attributing quit status to warning labels among male smokers in Thailand and all adult smokers in Thailand (versus *no* salience). *High label* salience was associated with increased odds of making a quit attempt among male smokers in Thailand, all smokers in Thailand, and male smokers in Thailand and Malaysia (versus *low* salience); and increased odds of attributing quit status to warning labels among male smokers in Thailand and all adult smokers in Thailand (versus *low* salience). A secondary goal of our research was to explore purchasing loose cigarettes, or loosies, as an effect modifier of the association between label salience and smoking outcomes. The investigation of loosies is imperative, as some researchers have raised concerns that smokers will employ avoidance tactics such as covering cigarette packs or purchasing loosies to avoid graphic labels. Our findings indicate that loosies are actually associated with *positive* smoking outcomes: among smokers reporting any label salience, we found reduced odds of high intensity smoking among smokers in Thailand and Malaysia who purchased loosies (versus those who did not purchase loosies). Among respondents who reported high salience, we found reduced odds of high intensity smoking among smokers in Thailand and Malaysia who purchased loosies (versus those who did not purchase loosies).

In conclusion, the findings of this study support the effectiveness of graphic cigarette warning labels in reducing intention to smoke and smoking behaviors among youth and adults in Southeast Asia. If current trends persist, tobacco will kill more than 8 million people worldwide annually by the year 2030, with 80 percent of these deaths in low- and middle-income countries. It is imperative that we continue to support the implementation of cost-effective public health policies to reverse these trends and reduce smoking-related morbidity and mortality.

Acknowledgements

Of all the components of this dissertation, I find myself struggling most with the acknowledgements. It is nearly impossible to find the words to express the extent of my gratitude for my family, friends, and mentors.

To my love, NAME REDACTED -- thank you for your patience and unwavering support throughout this process. Nothing brings a couple closer than simultaneously surviving a medical residency and a doctoral dissertation (not to mention planning a wedding, a cross-country move, and a career change). Late nights, weekends, and holidays spent writing at the coffee shop were made tolerable knowing that I was coming home to you (or one of your sweet notes on the bathroom mirror), cheering me along every step of the way. Thank you for riding out this rollercoaster with me.

To my mother – my fire, my heart, and my soul. Despite living in different states, your presence and support were tangible over these past five years. Speaking to you (every few hours!) helped keep me sane. I've learned so much from you about hard work and sacrifice. To say that this journey has been difficult would an understatement -- but you taught me that the ends justify the means. At the heart of everything I do is my innate drive to help others. You instilled compassion, beneficence, and empathy in me, and for that, I will be forever grateful. Kocham cię, always and forever.

To my father – my "Superman." Your battle with emphysema will not be in vain. Watching how hard you fight on a daily basis has inspired my commitment to conducting research on tobacco control policies in the hopes of preventing others from battling smoking-related disease. You can also take full credit for my love of math and statistics – because I certainly didn't get that from mom! You're so much more than "just a kid from Brooklyn" – you are my motivation, my inspiration, and my muse. Thank you for always being in my corner.

To Bill (Dr. Gallo) – my mentor, my compass, and, at times, my therapist. Thank you for taking me on as a mentee and for spending countless [espresso-fueled] hours cultivating me into the researcher I am today. I never would have been able to get through this process without your guidance and sage advice. It has been an honor to work with you, and to learn from you – and learn I did! From statistical methodologies, manuscript construction, and proper usage of pronouns, topic sentences, and transitions to the art of oil paintings, vintage hats, and ties – I have acquired so much knowledge and grown so much in these past few years. I will carry these lessons with me throughout my lifetime. Thank you from the bottom of my heart.

To Mimi (Dr. Fahs) – When I was contemplating applying to the CUNY DPH Program, I pulled up the profiles of all of the faculty members and was immediately struck by your impressive body of work.

We shared a common interest in tobacco policy research which led me to reach out to you via email. I'll never forget your response encouraging me to apply, or the warm welcome you gave me when I entered the program. I am still in disbelief that I have had the honor of working with you and the other esteemed researchers on my committee. Thank you for your guidance over these past five years.

To Nancy (Dr. Sohler) – I greatly admire your fiery spirit and passion for knowledge and science, as well as your research focus on underserved populations and health disparities. Though I never had the privilege of being a student in any of your courses, I was incredibly honored when you agreed to serve on my committee and impart your invaluable feedback and unique perspective as an esteemed epidemiologist. Thank you for always making yourself available via email and Skype while you were out of the country!

To Joel (Dr. Dubin) – I thank my lucky stars that Bill put us in touch a few years ago! Thank you for welcoming me to Waterloo and meeting with me to discuss SAS programming for longitudinal analyses. My apologies for my long, convoluted emails while I was in the process of de-bugging – I am grateful for your patience, and for your help dealing with my complex survey design. I must also thank you for introducing me to the ITC team. While I am not a believer in fate, I still cannot get over the fact that the ITC Project just happened to be housed at the University of Waterloo – only a few doors down from your office! Thank you for your time and invaluable feedback.

To my committee, *collectively* – thank you for bearing with my long, frantic emails – and for your advice, feedback, and guidance especially as I entered the final throes of dissertation completion. I will carry the integrity and wisdom you have imparted to me throughout my career as a public health scientist. It was a supreme honor and the highest of privileges to collaborate with each and every one of you.

Finally, I must thank the International Tobacco Control (ITC) Project Team, NAMES REDACTED, for taking the time to meet with me and for granting me access to the ITC South East Asia survey. It is only through the use of this incredible dataset that I have been able to answer the research questions I have had since I first learned about graphic cigarette warning labels.

Ultimately, I hope the knowledge gained from this dissertation will support efforts to curb smoking among adult smokers and prevent youth from ever picking up their first cigarette. As public health researchers, we must direct our attention to developing countries and vulnerable sub-populations which

have not experienced the same decrease in smoking as the Western world. The graphic warning labels on cigarette packs accurately portray the side effects of smoking, but they will never be able to truly capture the horrors of living with a smoking-related illness. Let us work to prevent the next generation from ever having to experience these horrors firsthand.

This one’s for you, dad.

Chapter 1. Introduction

1.1. Background and Significance

Despite progress in reducing prevalence of daily smoking over the past few decades, the number of smokers has increased steadily worldwide, and there are preliminary indications that global prevalence among men has increased in recent years [1]. Seventy percent of the world's 1.1 billion smokers are in developing countries, with over 50% in Asia alone [2]. The health and economic burden of tobacco use is rapidly shifting from high to low and middle income countries. Asia is an especially important region for global tobacco control given its large population and the trajectory of smoking rates in the region. If current smoking trends continue, tobacco use could cause approximately 8.3 million deaths annually by the year 2030, with more than 80% of deaths occurring in low- and middle-income countries (LMICs) [3], where nearly two-thirds of the world's smokers live [4]. The Southeast Asia region is home to nearly 400 million tobacco users, who experience about 1.2 million deaths annually [5]. Prevalence of smoking among men is especially high, in terms of proportion and absolute numbers [6]. Although women commonly use smokeless tobacco, the rising trend in smoking among women is causing grave concern among governments in the region [6]. Tobacco use among youth is quite high due to the tobacco industry's creative and targeted marketing strategies and its weak regulation [6]. Other key factors contributing to the tobacco epidemic in the region are abundant tobacco production, weak enforcement of tobacco control measures, and easy accessibility and affordability of tobacco products [6, 7].

Two Asian countries, Thailand and Malaysia, demonstrate different stages of tobacco control in this critical region. For more than a decade, Thailand has served as a model for tobacco control in Asia. In 1999, Thailand was one of the only Asian countries to experience a decline in smoking rates over the previous decade. It was one of the first countries to introduce comprehensive policies, including graphic (or pictorial) warning labels on cigarette packages which were implemented in March 2005. Despite progress, smoking rates remain high with 24% of Thai adults classified as smokers in 2011. Dramatic gender disparities exist among smokers with approximately 46.6% of Thai adult men reporting being daily smokers, as opposed to only 2.6% of Thai women [8]. Smoking rates also differ among rural and urban

populations; males who live in rural areas are more likely to smoke, whereas females living in urban areas are more likely to smoke [2].

Until recently, Malaysia had few comprehensive tobacco control policies and remained a tobaccofriendly country. In 2011, 23.1% Malaysian adults aged 15 years or older were current smokers. As in Thailand, there are dramatic differences in smoking rates between genders with approximately 43.9% of men reporting smoking, compared to only 1% of women. However, in recent years, Malaysia has made significant strides in tobacco control policy. New legislation was introduced in 2004 which restricted advertising and promotion, established smoke-free environments, and included measures to restrict access to minors. In January 2009, graphic warning labels on cigarettes replaced text-only warnings.

1.1.1. Graphic Cigarette Warning Label Policies in Thailand and Malaysia

In March 2005, Thailand became the fourth country in the world after Canada, Brazil, and Singapore to print graphic health warning labels on tobacco products. The original policy required six rotating graphics to cover 50% of the front and back of cigarette packages. In March 2006, nine new graphic warnings were put in place. In March 2010, Thailand updated the policy once again to require a new set of ten health warning images to cover 55% of the front and back of cigarette packages. These new labels contained quitline data for smokers trying to quit. In January 2012, a set of 10 different labels on the hazards and constituents were introduced. The new labels occupied 60% of each side of cigarette packs. In September 2013, the policy was updated once more to require graphic warning labels covering 85% of the front and back of cigarette packs, making Thailand's labels the largest in the world. New warning requirements for cigarettes were set to enter into force in October 2013, but tobacco companies were granted a request for a temporary suspension of the rules pending a final decision by the court on the merits of the case.

Thailand also prohibits the terms "light" and "mild" from appearing on packages, as they are considered misleading words that might cause consumers to believe that certain tobacco products are less dangerous than others or that may encourage consumption. In June 2011, Thailand released an

amendment of previous regulations banning the use of a list of misleading terms. Regulations now include a ban of words or terms which convey attractiveness such as "cool," "ice," "frost," "crisp," "fresh," "mint," "mellow," "rich," "smooth," "natural," "special," "genuine,", "luminous," "extra," "premium," and other terms with similar meaning.

On January 1, 2009, Malaysia became the fourth country in the Association of Southeast Asian Nations (ASEAN) region to implement pictorial health warnings after Singapore (2004), Thailand (2005), and Brunei (2008) [9]. Six rotating pictorial health warnings cover 40% of the front and 60% of the back of cigarette packs. Just as in Thailand, misleading descriptors on cigarette packs are also banned. Cigarette packs are also required to contain an advisory against selling to minors, and a quitline phone number for smokers interested in quitting. The six rotating graphics were adopted from labels required in Singapore and Thailand (three from each country). Warnings are printed in both Malay and English on each side of the pack, and are required to rotate every two years.

In February 2004, five years prior to the implementation of graphic cigarette labels, the “Tak Nak” (“Say No”) Campaign was launched by the Prime Minister of Malaysia in order to reduce the prevalence of smoking and smoking related morbidity and mortality. The campaign’s slogan “Every puff you take damages your body” was aimed at discouraging teenagers and women from starting to smoke, smokers from continuing to smoke, and friends and families to support activities to curb tobacco smoking. The campaign ran until 2011. Information and attitude/belief-change efforts were communicated through multiple media channels including television, newspapers, magazines, radio, cinema billboards, and through collateral items such as t-shirts.

1.1.2. Effectiveness of Graphic Cigarette Warning Labels

Previous research has suggested that the greater impact of graphic warning labels compared to text-only warnings is consistent across diverse racial/ethnic and socioeconomic populations. Given their great reach, graphic warning labels may be one of the few tobacco control policies that have the potential to reduce communication inequalities across groups. Policies that establish strong graphic warning labels

on tobacco packaging may be instrumental in reducing the toll of the tobacco epidemic, particularly within vulnerable communities [10].

Data from the International Tobacco Control (ITC) Policy Evaluation Project, a prospective longitudinal panel study of smokers in multiple countries [11, 12], demonstrate that graphic warnings are more likely to be noticed than text-only warnings [13-16], more effective in informing viewers of the risks of smoking [15, 17], and more likely to motivate quit-related activity [14, 18-20]. Experimental work is limited, but evidence suggests that graphic warnings outperform text-only warnings on a range of outcomes, including capturing attention [21], increasing awareness of health risks [22], and creating unfavorable associations with smoking [23], as well as perceived effectiveness [24, 25], negative affect [26], and motivation to quit [10, 22, 26, 27].

Other researchers point to shortcomings of the existing empirical evidence and are less convinced that graphic warning labels are effective in their intent to promote cessation. Ruiter and Kok [28, 29] argued that the evidence is sparse and unconvincing, and find flaws in the current research such as poor controls for mediating variables. They point out the lack of longitudinal evidence comparing attitudes toward smoking and smoking trends prior to and following the implementation of graphic labels in a specific population. Furthermore, there is some evidence that graphic warnings incite defensiveness in response to fear-arousing information [28, 30, 31]. Problems may arise when the fear induces a more pressing concern while curbing the immediate experience of fear, often by attempting to undermine the importance or credibility of the message. Self-affirmation theory [32] states that people are fundamentally motivated to protect their sense of self-integrity. This is the motive that is most aroused by threatening material, such as graphic warnings, and is satisfied by defensiveness [33].

Whether graphics or text-only warnings are implemented, message framing is central to the effectiveness of labels. According to the Prospect Theory [11], when people focus on potential gains they are not motivated to take risks or face uncertainty. Rather, they choose a definite gain over a potentially uncertain gain. However, when focusing on a loss, people are more likely to accept risk and uncertainty when the risk includes the possibility of avoiding a loss [34]. Loss-framed messages emphasize the

negative consequences of a behavior while gain-framed messages emphasize how one can avoid the undesirable outcome. The difference between gain framed avoidance and gain framed benefits is that the former emphasizes the threat one can avoid by not smoking while the latter emphasizes the pure benefits of not smoking [35]. Graphic cigarette labels have been criticized for being loss-framed, and have raised concerns of the incitation of avoidance tactics, such as covering cigarette packs or purchasing loose cigarettes, and possibly lead to other adverse effects [36].

Some research has suggested that warning labels would be more effective if they created a strong positive attitude toward quitting, while concurrently promoting a negative attitude towards smoking. An example of a message which promotes positive attitudes towards quitting is: “Quitting smoking reduces your chance of having a heart attack” or, “If you smoke two packs a day, quitting will save you *X* dollars in the next year” [37]. Furthermore, messages may only be relevant to specific segments of the population, e.g., adolescents and teenagers, current smokers, pregnant women, etc. The dissemination of information targeting specific subgroups has been shown to be more effective than generic messages [38].

With regard to process principles, color and brightness are one way to draw attention to warning labels; these tactics are also utilized by tobacco companies as a marketing technique. Bright colors tend to attract attention and prompt smokers to consider the content of the message. Bansal-Travels et al. [39] conducted a study to examine the potential impact of pack design on risk perception and brand appeal. Results showed that participants selected larger, graphic, and loss-framed warning labels as more likely to attract attention, encourage thoughts about health risks, motivate quitting, and be most effective. Participants were more likely to select packs with lighter color shading and descriptors such as light, silver, and smooth as delivering less tar, smoother taste, and lower health risk, compared to darkershaded or full-flavor packs.

Another issue, overexposure or wear-out, is a problem for any message that is presented repeatedly over time. A message’s effectiveness tends to increase over the first few exposures, but then diminishes over time [40]. Studies have found that people exposed to newly designed warnings are

significantly more likely to retain the message or concept of the newer warning label as compared with older labels [41]. A survey conducted in Canada in 1999 revealed that 65% of adult smokers and 74% of youth smokers agreed that the warning labels that were introduced in 1994 were "worn-out and had lost their effectiveness" [42]. Other studies found that individuals exposed to newly designed warnings were significantly more likely to remember the concept of the warnings than individuals exposed to old mandated warnings [43, 44]. Research has suggested that a variety of anti-smoking messages would be effective, and such a strategy would also address this over-exposure problem [37].

1.2 Overview of the dissertation

1.2.1. Innovation

Previous research on the impact of graphic cigarette warning labels has focused primarily on the adult response, particularly in Westernized countries such as Canada and Australia. Limited studies have investigated the impact on youth, and those that have investigated the youth response have primarily utilized cross-sectional designs, or were published before multiple waves of data became available. The longitudinal nature of the data that we utilize, as well as the analysis of multiple wave-pairs of repeatedmeasure data, strengthens the potential causal implications of findings and allows us to stratify by subgroups such as country, sex, and smoking status. The use of generalized estimating equations [45] to estimate our models accounts for the intra-subject correlation of responses over time and allows us to generate population-averaged (marginal) effects of graphic cigarette warning labels on smoking outcomes. This research builds upon prior research by examining the impact of the graphic warning label policy on youth and adult smoking *behaviors,* in addition to smoking *intentions*. Additionally, we examine the effects of graphic warning labels on different sub-classifications of smokers, including non- and neversmokers, who are just as likely, if not more so, to be confronted with warning labels as ad campaigns during a smoking decision scenario [46]. Furthermore, our models of youth and adult smoking are theory-driven, and include variables such as normative beliefs, self-efficacy (or perceived behavioral control), label saliency, peer and parental smoking, and societal influence (normative beliefs). We also explore varied measures of label salience and risk cognition after the implementation of graphic warning labels.

Lastly, to our knowledge, this is the first study to explore the moderating effects of purchasing loose cigarettes on smoking outcomes, as this may reduce exposure to the warning labels on cigarette packs.

1.2.2 Conceptual/Theoretical Framework

The underpinnings of behavior, or key predictors, and how to influence those predictors are integral to the discussion of public health message campaigns such as graphic cigarette warning labels.

Central to the design of graphic health warnings on cigarette packets is the intention to influence behavior by influencing its pre-cursers such as knowledge, attitudes, and beliefs. In order to conceptualize the mechanism through which graphic warning labels are effective, theoretical constructs from social psychology, social marketing, and health econometrics have been explored. The Health Belief Model (HBM) suggests that a person's decision to take a health action is influenced by her beliefs and perceptions [47]. Central to applying the Health Belief Model to this analysis is understanding the perceived threat of disease associated with smoking. Perceived threat is composed of both the perceived susceptibility to and seriousness of disease caused by certain actions. Related to the Health Belief Model is McGuire's Chain of Persuasion [48] which suggests that for a message to actually influence behavior, it must involve a sequence of cognitive responses: first a person must be exposed to the message; they must receive or attend to the message; they must comprehend the message; they must be persuaded by the message (yield to it); they must retain the message; they must retrieve it in relevant situations; they must decide to act; and, finally, act in accordance with the message itself. The Health Belief Model, as well as McGuire's Chain of Persuasion, emphasizes cognition, and the weighing up of opposing cognitions, in predicting health behavior. This model assumes that attitudes and behaviors are influenced by: a person's belief that they are susceptible to health consequences related to a behavior; a personal appraisal that those health consequences are serious; the person's perception that the behavior has more costs than benefits; and that there is some "cue to action" or precipitating force changing the current (implicitly balanced) state. However, a systematic review in 1992 found that the HBM lacked predictive power, probably due to its lack of scope in discussing other predisposing and enabling factors. The model was found to lack the predictive power of newer cognitive models. Two specific constructs missing from

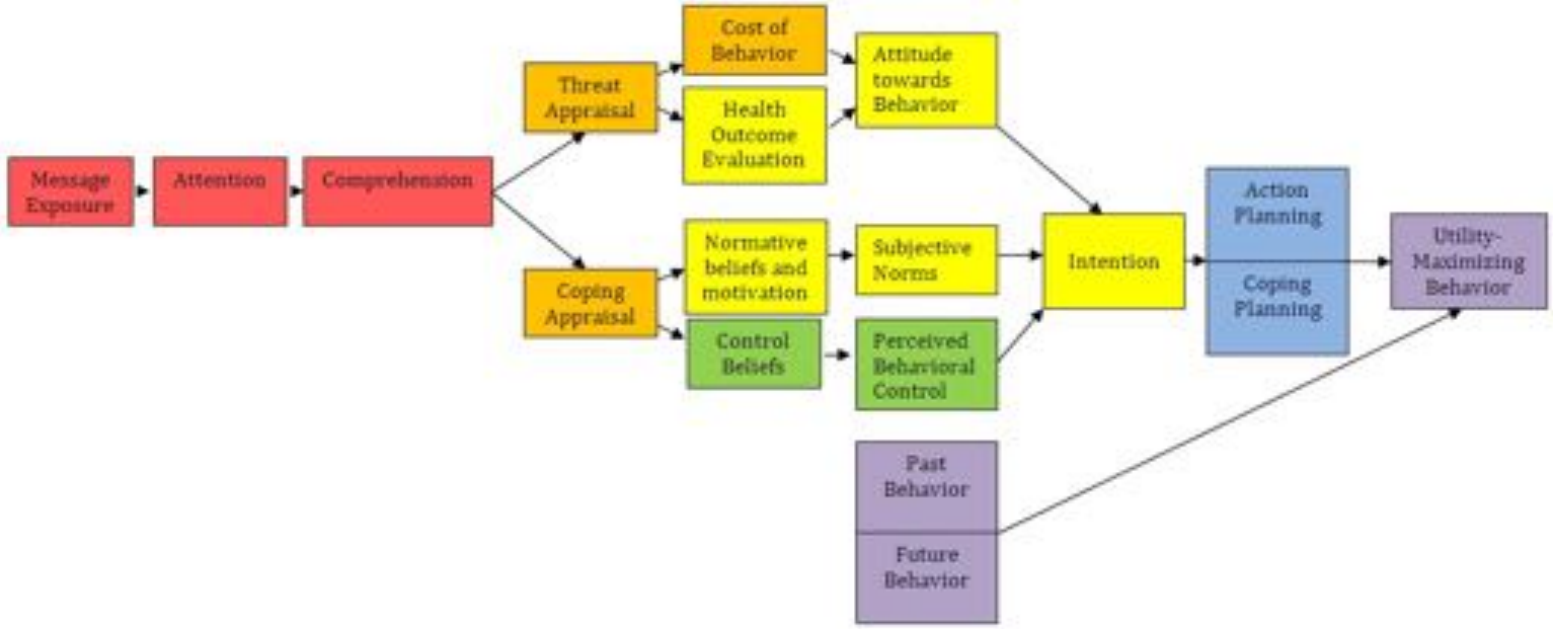
the model have become seminal in social cognitive theories and the study of health behavior change: efficacy beliefs and social norms.

Many behaviors, such as quitting smoking, are complex and require considerable motivation and skill. People's appraisal of their own capabilities, or self-efficacy, and the control they have over outcomes are held to be important. Albert Bandura's Social Cognitive Theory [49] argues that people's self-efficacy or belief in their ability to control an outcome, mediates their behavior. Self-efficacy is an important construct in the context of trying to promote quitting smoking as it is related to whether or not an individual will undertake particular goal-directed activities, the amount of energy that the individual will put into that effort, and the length of time that the individual will persist in striving to achieve a particular goal.

The construct of social norms refers to the conscious and unconscious conformity in peoples' everyday lives. It has been recognized by both social psychology and marketing theory that social conformity, or the tendency to want to be like relevant and significant others, is a fundamental component of human behavior. Social norms may have a direct impact on intentions which, in turn, may lead to a change in behavior. Within social norms, a subjective norm is a person's belief that most of their important others (i.e., peers, friends, etc.) think he or she should, or should not, perform the behavior in question. The individual takes into account the normative expectations and perceived support of others in their environment. Overall, it has been demonstrated that people are more likely to intend to perform a behavior, when they believe that other people who are important to them think it should be performed [50]. Incorporating social norms as a predictor of behavior change, the Theory of Reasoned Action [51] proposed that behavioral intention is determined by a weighted function of that individual's: (i) attitude towards performing that behavior **+** (ii) perceived subjective norms, or perceived social pressure to perform the behavior.

The Theory of Reasoned Action recognizes people as rational decision makers who make systematic use of the information available to them. Actions are largely seen to be made by choice and under an individual's control; additionally, a person's volitional behavior is held to be predicted directly by

an individual's intention to take action. The Theory of Planned Behavior [52] extended the Theory of Reasoned Action by incorporating self-efficacy or perceived behavioral control as a direct influence on intention and behavior. Perceived behavioral control is the extent to which the individual believes that taking the action will be hard or difficult. Most behaviors require skills, resources and cooperation of others to facilitate the behavior change, hence the addition to the model of (iii) perceived control over the behavior or self-efficacy.



Taking the Theories of Reasoned Action and Planned Behavior one step further, the Health Action Process Approach specifies a relationship between level of motivation to quit and degree of risk perceptions [53]. It proposes that there is a distinction between the pre-intentional motivation process (including risk perceptions) that leads to intention to make a behavior change and the post-intentional volition process that leads to the actual behavior change [53]. The volition process can be further subdivided into a planning phase, action phase, and maintenance phase. When applied to smoking cessation, the Health Action Process Approach predicts that those who do not intend to quit (nonintenders) should have lower risk perceptions than those who do intend to quit (intenders) [54].

The effectiveness of warning labels is thought to be determined, at least in part, by the graphicness of their design and content of their messages. While intended to communicate the risks of smoking, the labels may also evoke a fear response from smokers. The Protection Motivation Theory was developed to better understand fear appeals and how people cope with them. It proposes that we protect ourselves based on four factors: (i) perceived severity of a threatening event; (ii) perceived probability of the occurrence, or vulnerability; (iii) efficacy of the recommended preventive behavior; and (iv) perceived self-efficacy. Protection motivation incorporates both threat appraisal and the coping appraisal. Threat Appraisal consists of both the severity and vulnerability of situation; severity refers to the degree of harm from the unhealthy behavior, while vulnerability is the probability that one will experience harm. Additionally, rewards refer to the positive aspects of continuing the unhealthy behavior. The total threat represents the sum of severity and vulnerability, minus the rewards. Coping Appraisal consists of the response efficacy, self-efficacy, and the response costs. Response efficacy is the effectiveness of the recommended behavior in preventing harm; self-efficacy is the belief that one can successfully enact the

recommended behavior; and the response costs are the physical or psychological costs associated with the recommended behavior. Therefore, coping represents the sum of the response efficacy and selfefficacy, minus the response costs.

The theories described above borrow from the fields of social psychology and marketing; however, they do not necessarily take into account the fact that smokers are addicted to cigarettes, which affects their future smoking behavior. Rooted in the field of health econometrics, the Theory of Rational Addiction [20] suggests that addicts are 'rational' to the extent that they have a consistent plan to maximize utility over time and that their consumption decisions are made in light of the future consequences of those decisions. The Model of Rational Addiction expanded upon myopic models of addiction to include *future* consumption of addictive substance in its calculation of consumption: C(t) = f[P(t), C(t-1), C(t+1), Y(t), Z(t)]; where: P(t) is the price of the good at the current time period; C(t-1) is the consumption at a previous time period; C(t+1) is the consumption at a future time period; Y(t) represents income; and Z(t) represents preferences. According to the model, cigarette consumers must be aware of smoking's long-term health effects in order to take account of future impact of current consumption. The implicit effectiveness of messaging is conditioned upon an assumption of full information. Messages or cues are viewed as a means of potentially producing better outcomes in the consumption of tobacco and other sin goods. We may find that smokers have decreased marginal utility from smoking once the harms of smoking are communicated to them in this modality. Utilizing components of these behavioral theories, a conceptual framework has been developed to guide the investigation of the impact of graphic warning labels on smoking behavior (please see fig. 1.1).

Figure 1.1. Conceptual framework of the effectiveness of graphic warning labels on smoking outcomes.

Schematic presentation of McGuire's Chain of Persuasion (red); Protection Motivation Theory (orange); the Theory of Reasoned Action (yellow); the Theory of Planned Behavior (yellow plus green); the Health Action Process Approach (blue); and the Theory of Rational Addiction (purple).

Taking these behavioral theories together, it is hypothesized that the youth response to graphic cigarette warning labels may differ from the adult response for two main reasons: 1) the level of addiction is expected to be lower among youth due to less intense smoking history; 2) visual communication of risk may be more effective among youth, helping increase the perceived harms of smoking. These two factors combined are hypothesized to lower the utility of smoking in the eyes of youth. Adolescents are still undergoing cognitive changes, such as the transition from concrete thinking to more abstract thinking. Young teenagers will mainly believe what they can see or have experienced and, thus, they cannot fully appreciate the long-term or unseen consequences. The use of visual aids in communicating the risks of smoking may be viewed as a socially productive corrective device. Even in models of rational addiction, the implicit ineffectiveness of messaging is conditioned upon an assumption of full information. Graphic warning messages or cues are viewed as a means of potentially securing socially superior outcomes in the consumption of sin goods, such as cigarettes [55].

Furthermore, it is clear from targeted advertising campaigns put forth by Big Tobacco that models of smoking vary for youth and adults. The tobacco companies have recognized that teenagers have a

unique set of attitudes, social groups, values, aspirations, role models, and activities; tobacco companies attempt to infiltrate both their physical and social environments [56]. Tobacco companies spend billions of dollars each year to promote the use of their products in emerging markets. Direct advertising includes placing ads in broadcast, print, and outdoor venues. Indirect advertising include methods such as brand stretching, product placement, and point of sale where tobacco companies concentrate much of their advertising though product displays and product sales promotions. A report issued in March 2014 by the Campaign for Tobacco-Free Kids and other international public health organizations exposes how Philip Morris International's (PMI) 'Be Marlboro' marketing campaign uses themes and images that appeal to youth across the globe. The campaign has expanded to more than 50 countries despite being banned by a German court for targeting teens and generating similar complaints in other countries [57].

This dissertation examines the impact of a counter-advertising public health campaign, in the form of graphic cigarette warning labels, on intention to smoke, susceptibility to smoking, and behavioral

outcomes among youth and adults in Southeast Asia. For our youth sample, we use the Theory of Triadic Influence (TTI) [58, 59] to guide variable selection and model design. Using the TTI as a framework, we explore the influence of variables pertaining to three overarching domains of human behavior: social/normative, cultural/environmental, and intrapersonal. Specifically, we include variables within these constructs, including socio-demographic factors (e.g., age, sex, ethnicity), behavioral factors (e.g., peer, parental influence, and perceived societal norms), and personal factors (e.g., self-esteem, rebelliousness, and future discounting) in our model of youth smoking. The theory of Triadic Influence has been shown to successfully predict adolescent smoking behavior in previous research on youth smoking and other substance abuse [60-64].

We also seek to measure the effect of graphic cigarette warning labels on adult smoking behaviors, specifically smoking intensity, quit attempts, and successful cessation. Our adult model utilizes a different set of covariates than our youth model, as we recognize that different factors affect smoking among adults and youth. Variables in our adult model include known predictors of smoking behavior: sex [4, 65-67], age [4, 66, 68], race [67], level of education [69, 70], income [68, 69], self-efficacy [66, 68], level of addiction [68], smoking history [66, 68], smoking frequency (daily versus non-daily) [4, 68], type of cigarette smoked [factory-made (FM) versus roll-your-own (RYO)] [70, 71], and exposure to anti-smoking information or advertising [72, 73].

1.2.3. Specific Aims

Aim 1: Investigate the effect of Graphic Cigarette Warning Policies on Youth Smoking Intention in Malaysia and Thailand.

Sub-Aim 1: To assess the impact of the graphic cigarette warning label policy on youth in Thailand, stratified by sex and smoking status.

Sub-Aim 2: To measure the effect of the graphic cigarette warning label policy on youth behavioral outcomes (preliminary).

Approach: Utilize a quasi-experimental design to assess the impact of graphic warning labels implemented in Thailand, using Malaysia as a control.

Aim 2: Measure the Effect of Warning Label Risk Cognition on Youth Smoking Intention in Malaysia and Thailand.

Sub-Aim 1: To assess the effect of frequency of exposure, using risk cognition as a proxy, on youth smoking intention and susceptibility in Thailand.

Sub-Aim 2: To assess the effect of frequency of exposure, using risk cognition as a proxy, on youth smoking intention and susceptibility in Malaysia and Thailand.

Sub-Aim 3: To examine the effect of frequency of exposure, using risk cognition as a proxy, on youth smoking behavior among male youth in Thailand.

Approach: Limit data to the post-implementation phase in both countries. Conduct within-country analyses, as well as combine data to assess overall impact in Southeast Asia.

Aim 3: Investigate the Impact of Graphic Cigarette Warning Label Salience on Adult Smoking Behaviors in Malaysia and Thailand and Moderating Effects of Loosies.

Sub-aim 1: To assess the effect of frequency of exposure (using label salience as a proxy) on adult smoking behavior in Thailand.

Sub-aim 2: To assess varied levels of salience (any salience v no salience; high salience v low salience) and their impact on smoking outcomes among adult smokers in Thailand and Malaysia. Sub-aim 3: To assess the purchase of loosies as a potential effect modifier on label saliency. *Approach: Limit data to the post-implementation phase in both countries. Conduct within-country analyses, as well as combine data to assess overall impact in Southeast Asia.*

The three aims of this dissertation will ultimately inform three empirical papers. We examine the effect of the graphic cigarette warning label policy on smoking behaviors and behavioral intention among youth and adults, controlling for factors at the individual and population level. Sub-aims examine outcomes stratified by country, sex, as well as smoking status. We also explore different measures of cognition and salience of graphic warning labels on smoking outcomes. The moderating effects of purchasing loose cigarette (loosies) on the association between salience of graphic warnings and smoking behaviors are also explored. All three aims are addressed using a longitudinal study design utilizing the International Tobacco Control Southeast Asia (ITC-SEA) secondary dataset.

1.2.4. Organization of the dissertation

The subsequent part of the dissertation consists of four chapters. Chapter 2 assesses the impact of the graphic cigarette warning label policy among Thai youth using a quasi-experimental approach, with Malaysian youth serving as a control (aim 1). In Chapter 3, our focus is shifted to the post-policy implementation period in both countries. In an effort to assess the impact of frequency of exposure to graphic warning labels on behavioral intentions, smoking susceptibility, and smoking behavior, we utilize a measure of cognition of risk as an effective proxy (aim 2). These analyses build upon chapter 2 by closely examining cognition of risk, a mediator of the effect of warning labels on smoking outcomes. Chapter 4 focuses on the adult behavioral response to graphic warning labels using label salience as a proxy for exposure to graphic warning labels (aim 3). We also explore the moderating effects of loosies on the relationship between label salience and smoking behavior outcomes. Loosies are of particular importance due to concerns raised that graphic labels may elicit avoidance, defensiveness, and denial, and may lead to smokers taking measures to cover the cigarette packs or buy loose cigarettes ("loosies") to avoid exposure to warning labels. As such, we hypothesized that purchasing loosies might reduce the saliency of labels. Chapter 5 summarizes findings from Chapters 2-4 and discusses strengths and limitations of the study. The dissertation concludes with policy implications and recommendations for future research directions.

1.3 Data Source: International Tobacco Control Southeast Asia Survey

The ITC-SEA Survey is a cohort survey of nationally representative samples of adult smokers in Thailand and Malaysia. Eligible respondents originally included youth smokers and non-smokers (recruitment age 13-17 in Malaysia; age 13-19 in Thailand), adult smokers (age 18+) and adult nonsmokers in Malaysia (adult non-smokers in Thailand were not recruited in any waves). Individuals in jail, those living in institutions and non-citizens were ineligible. For both countries in every wave, the sample was designed to include: 2,000 adult smokers (or quitters who had been recruited as smokers) (age 18+); 1,000 youths (age 13-17, both smokers and non-smokers).

Respondents were surveyed using face to-face interviews and were recruited from households using a stratified multistage sampling design. The primary strata consisted of Bangkok and four regions (North, Northeast, Central, and South) in Thailand, and six zones of Malaysia. In Thailand, respondents were selected from Bangkok and two provinces in each of Thailand's four regions (Chiang Mai, Phrae, Nakhon Ratchasima, Nong Khai, Nakhon Pathom, Samut Sakhon, Nakhon Si Thammarat, and Songkhla). In Malaysia, respondents were drawn from one state in each of the country's six geographic zones (Kedah, Selangor, Johore, Terengganu, Sabah, and Sarawak) at Wave 1, and a seventh state, Penang, was added in Wave 2. In Malaysia, the feedback from Wave 2 showed that conducting face-toface surveys was costly, while phone penetration especially in urban areas was quite high. It was decided that for Wave 3 the majority of the interviews could be conducted by phone (about 80%) while in some rural areas, where the phone penetration is low, face-to-face surveys could still be used. Youth surveys were all self-reported; youth respondents completed a 30-minute self-administered (i.e., pen and pencil questionnaire). Respondents were instructed to complete the survey in a private area to ensure privacy from family members and were instructed to seal the survey in an envelope to maintain confidentiality and to encourage truthful reporting. Parental permission and youth consent were ascertained prior to surveying [74].

Wave 1 was conducted from January to March 2005 in both countries, Wave 2 from July to September 2006 in Thailand, about 14–18 months after the new warnings were introduced, and in Malaysia from August 2006 to March 2007. Wave 3 was conducted from January to March 2008 in Thailand, about 11 months after the second round of pictorial warnings came into effect, and from March to September 2008 in Malaysia. Wave 4 was conducted from April to July 2009 in Thailand, and July to November 2009 in Malaysia, about 7 months after pictorial warnings there were first implemented. Wave 5 was conducted from February to April 2011 in Thailand, approximately one year after the size of pictorial labels was expanded to 55% of the front and back of packs, and from May to April 2012 in Malaysia. Tables 1.1 and 1.2, below, display data collection dates and sample composition for Malaysia and Thailand.

Table 1.1. Data collection dates and sample composition of the ITC-SEA Malaysia survey.

ITC-SEA Malaysia Survey Collection

Wave	Survey Dates	Survey Sample
1	January to March 2005	2,004 Smokers, 1,555 Non-Smokers and 1,008 Youth
2	July 2006 to June 2007	1,640 Smokers and Quitters, 1,572 Non-Smokers and 777 Youth
3	February to September 2008	1,957 Smokers and Quitters, 1,486 Non-Smokers and 712 Youth
4	July to November 2009	2,045 Smokers and Quitters, 789 Non-Smokers and 878 Youth
5	May 2011 to April 2012	2,007 Smokers and 928 Youth

Table 1.2. Data collection dates and sample composition of the ITC-SEA Thailand survey.

ITC-SEA Thailand Survey Collection

Wave	Survey Dates	Survey Sample
1	January to March 2005	2,048 Smokers and 1,000 Youth
2	August to September 2006	2,158 Smokers and Quitters and 927 Youth
3	January to March 2008	2,607 Smokers and Quitters and 1,096 Youth
4	April to July 2009	2,430 Smokers and Quitters and 947 Youth
5	February to April 2011	2,175 Smokers and 963 Youth

1.4. Significance of the dissertation

The dire need for research on effective tobacco control policies is underscored by the shift of tobacco markets to developing countries. Strict regulation and the success of anti-smoking campaigns continue to hit tobacco firms' revenues in the Western world. Big Tobacco has shifted its focus on the few large markets that have growth potential and a relative lack of regulation, with Southeast Asia representing a prime opportunity. Tobacco firms see growth potential in the region's low rate of women

smokers. Across Southeast Asia, fewer than one in ten women smoke, compared with about 40-70% of men. A 2009 study across seven countries found that smoking rates were rising significantly among under-16 girls in the Philippines, Malaysia, Indonesia and Vietnam [75]. In Indonesia and the Philippines, tobacco companies have ramped up advertising to young girls, with tactics such as selling cigarettes in small “lipstick packs” that seek to capture the glamour of high-end cosmetics. Countries struggling with widespread poverty and unemployment may be reluctant to clamp down on an industry that provides revenue and employment. However, they are also, slowly, coming to recognize the health-care costs associated with smoking, and the human suffering from tobacco-related disease [75].

Worldwide, smoking kills nearly six million people annually. More than five million of these deaths are the result of direct tobacco use, while more than 600,000 deaths are the result of non-smokers being exposed to second-hand smoke. A total of 8.6 million people currently suffer from smoking-caused illness. Over 70% of deaths from bronchial, tracheal, and lung cancer are attributable to tobacco use. Compared to nonsmokers, smoking increases the risk of men developing lung cancer by 23 times; of women developing lung cancer by 13 times; and of either sex dying from COPD by 12 to 13 times [1]. Approximately 90% of chronic obstructive pulmonary disease (COPD) deaths are caused by smoking [2, 3]. There is no question that policies to reduce smoking, if successful, will reduce the burden of lung disease, and save countless lives. One such policy, the implementation of graphic cigarette warning labels, has been somewhat controversial, mainly due to the dearth of research investigating the effectiveness of graphic cigarette labels in influencing smoking *behavior*, particularly in developing countries where the need for tobacco control policies is crucial.

Research on the advantages of graphic versus text-only warnings has only rarely addressed the issue of differential effects across population subgroups. Research on the effects of graphic warnings among populations in developing countries is critical to ensure that this policy addresses, or at least does not exacerbate, tobacco-related health disparities. A growing body of research has shown that disadvantaged groups may differ in their ability to access, process and act on health information–a phenomenon that has been characterized as communication inequality [76]. Studies have documented substantial communication inequalities in access to and processing of information across population

subgroups [76-78], particularly for lower SES groups. Such inequalities often parallel disparities in smoking-related health knowledge and health outcomes. [26]–[30] Although incompatibility between the level at which information is presented and the audience's level of literacy and numeracy is typically cited as an important factor, [31], [32] other factors also may influence processing, including differences in the type of messages that attract viewers' attention, varying interpretation of messages, and variation in the perceived credibility of messages. [33]–[35] Yet the belief that a health message is credible, or the type of message that grabs a smoker's attention and motivates intentions to quit, may be linked to factors related to an individual's social class, education or racial/ethnic background [10].

The goal of this research is to evaluate the impact of graphic warning labels on smoking behavior, which will ultimately affect the lung and overall health of the population. Smokers report that their main source of risk information is obtained from cigarette packages more than any other source, except for television campaigns [4, 5]. Pictorial warnings may be particularly important in communicating health information to populations with lower literacy rates [4], as well as youth. It has been estimated that over 6 million children under the age of 18 alive today will ultimately die from smoking, unless smoking rates decline. Every day, more than 3,000 youth under the age of 18 try smoking for the first time; and an additional 700 youth become regular daily smokers [6]. Understanding the effectiveness of graphic warning labels among youth, taking into account the underpinnings of smoking behavior, or key predictors, and how to influence those predictors, is integral to the goal of reducing the enormous toll of lung disease on health care costs and quality of life.

The overarching aim of this research is to measure the effect of graphic labels as a tobacco policy, focusing on youth. It is widely accepted that the majority of smokers began the habit in their teenage years; seventy percent began smoking regularly at age 18 or younger [7]. If graphic labels prove effective among youth, evidence-based and cost effective tobacco policies could significantly reduce lung disease by preventing a generation of smokers from forming. This research represents a timely step to advance knowledge of the effectiveness of graphic labels, as well as the determinants of effectiveness, e.g. whether effectiveness varies by sociodemographics, past behavior, personality, and environmental factors.

The strength, innovation, and significance of this dissertation research can be summarized in three ways: 1) the focus of policy effectiveness graphic cigarette labels addresses one of the highest public health priorities for tobacco control and the prevention of tobacco-related lung disease, e.g. youth smoking initiation; 2) the comparative assessment of Thailand and Malaysia develops original, unique, and timely information for global health policy decision makers, especially in developing countries; and 3) the advanced quantitative methodology proposed takes advantage of newly available longitudinal data, thus allowing a rigorous design to better understand behavioral and environmental determinants of policy effectiveness. If graphic warning labels are found to be effective in reducing smoking behavior, these findings may be used to support their implementation in other countries where they are currently not

mandated. If effective, pictorial labels would represent an inexpensive, far-reaching policy intervention with a high frequency of exposure that has the potential of saving billions of lives.

Chapter 2. The Effect of Graphic Cigarette Warning Policies on Youth Smoking Intention in Southeast Asia: Results from International Tobacco Control Project

2.1. Introduction

The health and economic burden of tobacco use is rapidly shifting from high- to low- and middleincome countries. Seventy percent of the world's 1.1 billion smokers live in developing nations, with over 50% in Asia alone [79]. The tobacco burden is especially high in the World Health

Organization's SouthEast Asia Region (SEAR), making it an especially important region for global tobacco control given its large population and upward trajectory of smoking rates [80].

Two SEAR countries, Thailand and Malaysia, demonstrate different stages of tobacco control in this critical region. For more than a decade, Thailand has served as a model for tobacco control in Asia, introducing comprehensive policies, including graphic (or pictorial) warning labels on cigarette packages, in March 2005. Overall, 55% of the package space was appropriated to the graphic warnings which included six rotating messages. Thailand has since updated health warnings regularly with regard to size and content of graphic images. Even so, 24% of Thai adults (defined as individuals aged 15 years or older) reported being current smokers in 2011, translating to 13 million individuals, predominantly men; that year, 46.6% of Thai adult men reporting being daily smokers, as opposed to only 2.6% of Thai women [8]. With regard to youth smoking, a total of 11.7% of youth (defined as individuals under the age of 15 years) reported smoking cigarettes in 2009. Similar gender disparities among adult smokers exist among youth, with 20.1% of boys and 3.8% of girls reporting smoking [81].

Malaysia, dissimilarly, has had until recently few comprehensive tobacco control policies, and has thus remained a tobacco-friendly country. In 2011, approximately 23.1% of Malaysians reported being current smokers. As in Thailand, there exist dramatic gender disparities among smokers, with 43.9% of men reporting smoking, as compared to only 1% of women [82]. With regard to youth, 18.2% of Malaysian youth reported being current smokers in 2009, with a gender breakdown of 30.9% of boys and 5.3% of girls [81]. Nevertheless, in recent years, Malaysia has made significant strides in tobacco control policy including the implementation of six rotating graphic warning labels in January 2009. Graphic warnings are required to cover 40% of the front and 60% of the back of all cigarette packages, equating to 50% of the overall package space.

2.1.1. Youth Smoking and Vulnerability

Previous research on Thai and Malaysian youth indicates that smokers try their first cigarette at an average age of 14 years. Smokers in each country reported smoking their first cigarette as early as 8 years of age, with almost one-fifth of smokers trying their first cigarette before 13 years of age [83]. Among youth, factors that influence early trials with cigarettes may be separate from those that influence

progression and persistence; notably, peer influences emerge as powerful motivators of behavior change during adolescence [84]. Adolescence and young adulthood encompass critical social transitions to full adulthood, wherein youth extend risk-taking as they sample and, in some instances, acquire adult behaviors. These periods thus comprise a unique window of vulnerability for tobacco use onset. Nonetheless, risk-taking is a single, though complex, component of multi-determined, behavior. Cigarette smoking is influenced by a broad set of distinct and overlapping biological, psychosocial, and environmental factors. The putative efficacy of graphic warning labels derives from the successful use of 'fear appeals' to communicate risk [85], emphasize loss avoidance and risk aversion [37], and increase message retention [86]. The cognitive ability of youth to respond to such mechanisms is, however, questionable. For example, adolescents and teenagers possess high 'discount rates,' that they are more likely than adults to systematically undervalue future consequences of their current behavior [87]. In addition, brain development in adolescence remains incomplete, as the prefrontal cortex, which controls reasoning and impulses, is not fully developed until the age of 25 [88]. We hypothesize that visual communication of risk may help significantly increase the perceived harms of smoking, thus reducing smoking intention among youth.

2.1.2. Effectiveness of Graphic Cigarette Warning Labels

Conceptual arguments for the implementation of graphic cigarette warning label assert their influence on behavior via pre-cursers, such as knowledge, attitudes, and beliefs. Theoretical research in public health and psychology suggest that graphic cigarette warning labels may effectively communicate the risks associated with smoking, serving as a cue for behavioral change such as cessation and decreased intensity, or even as a preventive measure to hinder smoking initiation, which is especially relevant to youth populations. Although extensive research has been conducted on the adult behavioral response to graphic warning labels enacted in Canada, Australia, and other Western countries, there is a dearth of studies in developing countries. There are even fewer studies on the effect of graphic warning labels on *youth* smoking behavior, which is surprising given that smoking initiation most often occurs during youth and young adulthood, and early initiation is associated with a greater dependence and higher mortality from smoking-related diseases [89-91]. The goal of our research is therefore to assess

the effect of warning label policies on youth smoking intention in Thailand and Malaysia. Additionally, we conduct preliminary analyses of youth smoking behavioral outcomes, however, power is limited due to the small sample of youth smokers. To our knowledge, this is the first study to utilize longitudinal data to conduct cross-national analyses of the effect of graphic warning labels on the youth response.

Among adults, there is substantial evidence favoring the effectiveness of graphic health warnings [14, 20, 92-99], specifically with regard to intentions to quit, thoughts about health risks, decreased smoking prevalence, and cessation behavior [92, 100, 101]. Studies have shown that large graphic warning labels on cigarette packages are an important source of health information for smokers and nonsmokers [37]. Exposure to graphic labels has been shown to reduce cigarette packet appeal [26],

increase health knowledge, awareness and perception of risks associated with smoking [13-15, 17, 20, 94, 95, 100, 102], strengthen intentions to quit [94], encourage quit attempts [13, 20, 26, 100, 102], increase use of quitlines [95], prevent relapse [103], discourage smoking initiation [26, 100, 102] and decrease the odds of being a smoker [20, 101].

The limited evidence on the effectiveness of warning labels in developing countries suggests similar findings to those in Western countries. An experimental study conducted in Malaysia suggested that graphic labels had a greater impact positive impact than text-only labels [22]. Similarly, an experimental study in China found that adult smokers were more likely to rate graphic versus text-only labels as more effective in motivating smoking cessation and preventing smoking among youth [104].
Other studies have supported graphic labels' impact on cognitive and behavioral reactions and interest in quitting [16, 105]. A study by Yong et al. (2013) utilized a quasi-experimental design to assess the impact of graphic labels in Thailand, using Malaysia as a control, as pre-graphic label implementation data were utilized for comparison purposes. Thai smokers' awareness and cognitive and behavioral reactions increased markedly after the introduction of graphic labels, with effects sustained at follow-up; by contrast, no significant change was observed in Malaysia over the same time period [71].

The majority of research on the youth response to graphic warning labels consists of preimplementation, experimental studies. Several of these studies have found that graphic labels

positively affect the smoking knowledge, attitudes, and beliefs among adolescents [102, 106-109]. Post-policy implementation research on the youth effects of graphic cigarette warning labels is far more limited, but is suggestive of warning labels' effectiveness among adolescents and young adults [96, 99, 102, 106, 108111]. One study conducted in Australia suggests that graphic warning labels increased cognitive processing, with youth more frequently reading, attending to, and talking about labels at follow-up (versus text-only labels). Experimental and established youth smokers reported thinking about quitting and forgoing cigarettes at follow-up [99]. A Greek study of adolescents found that graphic warning labels were more effective than text-only labels in informing youth about health effects of smoking and preventing initiation [96]. Research has found that graphic labels are more effective than text-only labels in motivating youth smokers to quit and ex-youth smokers to remain quit [102]. However, there are contradictory studies that have found that adolescents do not report seeing or remembering graphic labels more than text-only labels, and that awareness of graphic labels is not associated with reduced smoking [106]. Another study has suggested that adolescents do not believe graphic health warnings will influence adolescents who already smoke [109].

Conceptual arguments against the implementation of graphic warning labels relate to avoidance, defensiveness, and denial. Some studies have found that graphic warning labels are not effective in their intent to promote cessation and reduce smoking behavior. Furthermore, there is some evidence that graphic warnings incite defensiveness in response to fear-arousing information [28, 30, 31]. Problems may arise when the fear induces a more pressing concern while curbing the immediate experience of fear, often by attempting to undermine the importance or credibility of the message. Self-affirmation theory [32] states that people are fundamentally motivated to protect their sense of self-integrity; this is the motive that is most aroused by threatening material, such as graphic warnings, and is satisfied by defensiveness [33]. The tobacco industry has suggested that the use of large pictures may reduce the effectiveness of health warnings and could actually lead to increases in smoking behavior; however, there is no evidence that pictorial warnings lead to 'boomerang' effects [112]. Comprehensive cross-national studies have found that the Australian pictorial warnings, introduced in 2005, led to greater avoidant behaviors (e.g. covering up the pack, keeping it out of sight, or avoiding particular labels), compared to

Canada, the United Kingdom, and the USA [13, 14]. Importantly, however, those smokers who engaged in avoidant behaviors were no less likely to intend to quit or to attempt to quit [13], replicating the findings of a study of the Canadian warnings [93]. With regard to empirical flaws, Ruiter and Kok [28, 29] argue that the evidence of the effectiveness of graphic warnings is sparse and unconvincing, and find flaws in the current research such as poor controls for mediating variables. They point out the lack of longitudinal evidence comparing attitudes toward smoking and smoking trends prior to and following the implementation of graphic labels in a specific population.

Graphic warning labels have been investigated in relation to changes in smoking intention and behavior among adults and youth, although there are few post-policy implementation studies on youth. Furthermore, the majority of research on this topic relies upon data collected *after* the introduction of warning labels, without any pre-policy implementation data for comparison. While there do exist

experimental studies conducted on graphic warning labels, most are limited with regard to external validity. Given that package warning labels are introduced at the national level, and that countries cannot be randomized to different conditions, it is simply not possible to conduct experimental research on the implementation of pictorial warnings. The most rigorous alternative would be a quasi-experimental research design that includes pre- and post-evaluations, across several countries that can serve as comparison groups. Such designs are high in both internal and external validity [113]. Hammond et al. [13] conducted one such study comparing the effectiveness of cigarette warning labels among adults in Australia, Canada, the United Kingdom, and the United States. Our study similarly addresses gaps in the literature by measuring behavioral change pre- and post- policy implementation among youth in Malaysia and Thailand using a quasi-experimental design. To our knowledge, this is the first study to conduct longitudinal assessment of the youth behavioral response to graphic warning labels utilizing pre- and post – implementation data. Furthermore, this study addresses the following gaps in the current literature on graphic warning label policies: 1) lack of longitudinal studies utilizing pre- and post- policy data; 2) lack of measurement of behavioral intention or behavioral change among youth 3) lack of studies on the effectiveness of graphic warning labels in Southeast Asia.

2.2. Methods

2.2.1. Data source

This study utilized nationally representative data from the International Tobacco Control South East Asia (ITC SEA) survey. Details on the conceptual framework of the ITC Project and its methodology have been published elsewhere [11, 12]. Briefly, the ITC SEA survey is a prospective, longitudinal, cohort survey of youth and adults in Thailand and Malaysia. Eligible respondents originally were youth smokers and non-smokers (recruitment age 13-17 in Malaysia; age 13-19 in Thailand), adult smokers (age 18+) and adult non-smokers in Malaysia; adult non-smokers in Thailand were not recruited in any waves. As this study examines the youth response, adult subjects were excluded from the sample. Respondents were surveyed using face to-face and phone interviews, and were recruited from households using a stratified multistage sampling design. Information on the complex sampling design have been detailed by Yong et al. (2013) [71]. Youth surveys were all self-reported; youth respondents completed a 30-minute

self-administered (i.e., pen and paper questionnaire). See table 2.1 for data collection dates and sample composition for the five waves of ITC-SEA surveys. See figures 2.1 and 2.2 for a timeline of tobacco policies and ITC survey data collection waves in Thailand and Malaysia, respectively.

2.2.2. Measures

2.2.2.1. Primary Outcome Variables: Behavioral Intentions, Susceptibility, Label Salience, and Cognition of Risk

Youth behavioral intentions were measured by the following variables: plan to *smoke* (measured among non-smokers, never-smokers, and current smokers) and plan to *quit* within one month and within six months (among smokers). **Plan to smoke,** a binary variable, was assessed based on participant responses (four-point ordinal scale) to the following question: “At any time during the next year do you think you will smoke a cigarette?” The responses “probably yes” and “definitely yes” were coded 1 (i.e., plan to smoke in the following year); the remaining responses (“probably no” and “definitely no”) were coded 0 (i.e., no plan to smoke in the following year). **Plan to quit,** among smokers, was also a binary variable. It was assessed based on responses to the following survey question: “Which of the following describe your thoughts about quitting smoking?” Responses comprised: “I plan to quit in the next 30 days

[1 month]"; "I plan to quit sometime in the next 6 months"; "I plan to quit, but not in the next 6 months"; and "I do not plan to quit at all". Respondents who reported planning to quit within the next 30 days or 6 months were coded 1; all those who reported not planning to quit were coded 0.

Smoking susceptibility, among non-smokers (including former and never-smokers), was a binary variable based on responses to two survey questions, each of whose responses were on a fourpoint ordinal scale (responses: definitely yes, probably yes, probably not, definitely not). The questions were: 1) "If one of your best friends were to offer you a cigarette, would you smoke it?" and 2) "At any time during the next year, do you think you will smoke a cigarette?" Participants who answered "definitely yes," "probably yes," and "probably not" to either question were coded 1, indicating susceptibility. Otherwise, respondents were coded 0, suggesting non-susceptibility. The coding scheme for susceptibility was developed by Pierce et al [114], and has been utilized by similar research on youth smoking in Southeast Asia [115].

Label salience, known in this literature as "noticing" labels, was measured by the survey item: "In the last month, how often, if at all, have you noticed health warnings on cigarette packages?" Participants who answered "very often" or "often" were coded 1, suggesting salience. Otherwise, respondents who answered "never" or "once in a while" were coded 0.

Cognition of risk, among participants who reported ever noticing labels, was assessed by the survey item: "To what extent, if at all, have the health warnings made you think about the health risks of smoking?" Respondents who answered "a lot" were coded 1, indicating high cognition. Participants who answered "a little" or "not at all" were coded 0.

2.2.2.2. Secondary Outcome: Smoking Behavior

Smoking behavior is measured by 5 separate variables: smoking initiation, high-intensity smoking, quit attempt, increased smoking intensity, and reduced smoking intensity. **Smoking initiation,** a binary variable, takes the value 1 where non-smokers at the baseline wave report smoking at follow-up.

Smokers at follow-up include participants who reported smoking more than 100 cigarettes in their lifetimes and at least one cigarette in the last 30 days. **High intensity smoking,** among smokers, is a binary variable that takes the value 1 if respondents report smoking 10 or more cigarettes per day, and 0 if respondents report smoking 9 or fewer cigarettes per day. **Quit attempt,** among baseline smokers, is a binary variable that takes the value 1 if respondents indicated that they attempted to quit smoking in the last year (responses "in the last month" and "in the last year" combined). Changes in smoking intensity, among smokers, was measured by two binary variables: **increased intensity** and **decreased intensity.** Increased intensity was coded 1 if daily cigarette consumption at follow-up was greater than that at baseline, and 0 otherwise; decreased intensity was coded 1 if baseline consumption was greater than that at follow-up. Intensity at both waves was measured by ordinal, categorical, variables.

2.2.2.3. Independent Variable of Interest: Warning Label Policy (Country)

To assess the effect of the graphic warning label policy on smoking outcomes, we use 'country of residence' as a proxy for the implementation of the policy. We limit our data to wave-pairs 2 and 3 which captures the pre-implementation period in Malaysia and post-implementation period in Thailand. As such,

Thailand represents the experimental group and Malaysia serves as a control in our quasi-experimental design. Therefore, differences in smoking outcomes in Thailand versus Malaysia (reference group), should reflect the impact of the graphic cigarette warning label policy, after controlling for covariates.

2.2.2.4. Control Variables

The potential set of basic control variables comprise gender (female=1), age (proxied by being of legal smoking age follow-up=1), religion (3 dummy variables: Islam, Buddhism, and other (referent)), ethnicity (majority group vs. minor group (referent)), and urban/rural status (rural=referent). Ethnic minority status and urban/rural status were obtained from the household enumeration, which was completed by an adult informant. Religion and ethnicity were ultimately omitted from GEE analyses, as they were highly correlated with country of residence, as participants from Malaysia are primarily Islamic and Malay, and participants from Thailand predominantly Buddhist and Thai. We also control for cohort

(the wave in which participants were first recruited into the ITC Project) and wave-pair, which are an attempt to account for secular changes in smoking attitudes and behavior.

2.2.2.5. Additional Covariates

A set of additional control variables account for cultural/attitudinal, social/normative, and intrapersonal factors. Such factors, derived from the Theory of Triadic Influence (TTI) [58, 59], have been shown to predict adolescent smoking behavior in previous research on youth smoking and other substance abuse [60-64]. **Cultural/attitudinal** variables encompass the demographic variables previously outlined. **Social/normative** variables included: peer smoking, smoking at home, and perceived societal norms. Peer smoking was assessed by responses to the question: "Of the five closest friends that you spend time with on a regular basis, how many of them are smokers?" A response of 0 friends was the referent category. [No] smoking at home was measured by the survey item: "During the past 7 days (one week), how often have people smoked inside your home while you were there?" Responses comprised: "never," "sometimes," and "often." Respondents who answered "sometimes" or "often" were coded 0, indicating smoking at home (referent). A measure of perceived societal norms was constructed based upon level of agreement with the statement: "Society disapproves of smoking." Responses comprised: "agree," "in-between" and "disagree" (referent).

Intrapersonal factors included: self-esteem, rebelliousness, and future discounting. Self-esteem was a binary variable assessed by the survey item: "Choose one statement below that best describes you in the past two weeks, including today." Respondents who answered "I hate myself" or "I do not like myself" were coded 0, suggesting low self-esteem (referent). Respondents who answered "I like myself" were coded 1, indicating high self-esteem. A binary measure of rebellion was assessed by the survey item: "I do things my parents would not want me to do." Respondents who answered: "never" or "sometimes" were coded 0, indicating little or no rebelliousness (referent). Respondents who answered "often" were coded 1, indicating rebelliousness. Future discounting was assessed by level of agreement to the statement: "I spend a lot of time thinking about how what I do today will affect my life in the future." Participants who responded "agree" were coded 1 indicating a low discount rate. Respondents who answered "in-between" or "disagree" were coded 0 indicating a low discount rate (referent).

2.2.3. Analysis

2.2.3.1. Descriptive Analysis

Univariate statistics were used to describe the sample. Results are stratified by country (Malaysia and Thailand), as well as smoke status (non-smokers and smokers). We present frequencies as well as sample proportions displayed as column percentages.

2.2.3.2. Inferential Analysis

We used data from four years (2006-2009) of the ITC-SEA. The data were arranged in two wavepairs, in which we combined contiguous baseline and follow-up data.

Wave-pair 1	**Wave-pair 2**	**Wave-pair 3**	**Wave-pair 4**
Wave 1 + Wave 2	Wave 2 + Wave 3	Wave 3 + Wave 4	Wave 4 + Wave 5
TH: Jan 2005 – Sept 2006	TH: Aug 2006 – Mar 2008	TH: Jan 2008 – July 2009	TH: Apr 2009 – Apr 2011
MY: Jan 2005 – June 2007	MY: Aug 2006 – Sept 2008	MY: Feb 2008 – Nov 2009	MY: Jul 2009 – Apr 2012

The 2006-2009 period reflects a policy environment in which Thailand had enacted graphic cigarette warning labels (i.e., existed in post-policy period) and Malaysia had not (i.e., was in pre-policy period).

Equation (1) depicts the relationship between our smoking outcomes and policy differences across Thailand and Malaysia.

$$\text{Logit}(P(\text{SMOKING OUTCOME}_{it})) = \beta_0 + \beta_1 \bullet \text{COUNTRY}_i + \beta_x \bullet X_{i(t-1)} \quad (1)$$

In our model, SMOKING OUTCOMES, which were measured at follow-up (time t), were regressed on COUNTRY (the time-consistent policy proxy), and a vector of covariates (X), which were lagged to the baseline (t-1) of each data wave-pair, and β_0 is the regression constant. We estimated the models with Generalized Estimating Equations (GEE) models, which generate population-averaged (marginal) effects of graphic cigarette warning labels on smoking outcomes. GEE is preferable to other techniques (e.g., fixed effects regression) for several major reasons. First, it corrects for intra-subject correlation that arises from repeated-measures data. Second, it estimates population-averaged coefficients directly from observed data without restrictive assumptions about heterogeneity across individuals in the parameters [116]. Third, it accommodates dependent variables of various distributions

(e.g., linear, logit, count, etc.). Finally, it permits the overt estimation of regression parameters on timeindependent covariates, whose effects on the outcomes may be of interest to the investigator or policymaker.

We fitted separate, gender-stratified, models of the effect of graphic cigarette labeling for each smoking outcome. In accordance with the Theory of Triadic Influence (TTI), the models were built in a partially hierarchical fashion, wherein we added a theoretically linked set of covariates at each stage in the process, while removing the set that was added in the previous step. The first, benchmark, model specification included the policy variable (Thailand =1; Malaysia = referent) and demographic controls (cultural/attitudinal factors); the second specification added social/normative variables to the initial specification; the third, and final, specification added intrapersonal factors to the first specification, but omitted the social/normative set. All models controlled for wave-pair (i.e., time) and cohort. Only crude, unadjusted models, were fitted for smoking behavior, as an insufficient number of youth smokers precluded model convergence when covariates were controlled. Smoking behavior models were, moreover, estimated only among male youth, due to the low prevalence of smoking among female youth in both Thailand and Malaysia. The decision to stratify is based on documented disparities in smoking across men and women [8, 81, 82]; this decision was further supported by the results of tests of sex differences in our models. In pre-estimation testing, we observed statistically significant ($p>0.0001$) coefficients on country x gender interactions in all model specifications.

Our analyses were conducted using SAS-Callable SUDAAN version 11.0.1 to account for the multistage sampling design and oversampling used in the ITC-SEA Project and the longitudinal nature of the data. Analyses were conducted using unweighted and weighted data for all models, with no significant differences observed between weighted and unweighted analyses. Results are presented for weighted analyses, with standard errors and model coefficients adjusted accordingly. As all outcomes are binary, we generate odds ratios and 95% confidence intervals. The QIC (Quasi-likelihood under the Independence model Criterion) statistic was used for comparing models fit with likelihood-based methods among otherwise equally suitable structures.

2.3. Results

Table 2.2 contains summary statistics for country-stratified sample by smoking status.

Approximately 5.56% of the Malaysian sample and 10.30% of the Thai sample reported being current smokers at follow-up. Other relevant information may be obtained from Table 2.2. Tables 2.3 and 2.4 present gender-stratified results of regressions that estimated the association between smoking outcomes and graphic cigarette labeling (proxied by country; Thailand=1), specifically, plan to smoke and smoking susceptibility, and label salience and cognition of risk, respectively. The regression models were estimated among relevant groups of participants. (For example, analysis of "plan to quit" is performed among current smokers only, whereas analysis of "susceptible to smoke" is conducted exclusively among non-smokers and never-smokers.) Once more, three model specifications of smoking behavioral intention were modeled using the Theory of Triadic Influence (TTI) as a framework [58, 59]. Independent effects of adjustment variables are specified in relevant tables.

2.3.1. Smoking Intention and Susceptibility

In Table 2.3, we present results for the smoking intention outcomes (**plan to smoke** and **plan to quit)** and **smoking susceptibility.** Our measure of 'plan to smoke' has different implications for our three classifications of smokers (non-smokers, never-smokers, and current smokers). Planning to smoke *among non-smokers or never-smokers* is effectively a measure of intention to *initiate* smoking, whereas planning to smoke among current smokers is a measure of intention to *sustain* the habit. With regard to plan to smoke the following year among male non- or never-smokers, country effects were not significant. Thus, graphic cigarette labeling is not associated with smoking initiation when cross-national data are used to proxy the policy effect. Nevertheless, among male smokers, country effects were highly significant for model 1 [OR=0.19, 95% CI (0.08, 0.46)], model 2 [OR=0.16, 95% CI (0.06, 0.42)], and model 3 [OR=0.17, 95% CI (0.06, 0.46)], implying that living in Thailand significantly reduced the odds of planning to *continue* smoking by roughly 50%. Alternatively, among females, significant country effects were found among non-smokers and never-smokers in model 1 [OR=0.35, 95% CI (0.12, 0.97)], model 2 [OR=0.30, 95% CI (0.11, 0.82)], and model 3 [OR=0.25, 95% CI (0.09, 0.72)]. In this case, living in Thailand reduced odds of planning to smoke by between 65% and 75% compared with living in Malaysia. (Please note that results for female non-smokers and never-smokers are equivalent, as there were no female "former smokers" in the sample which would have inflated the number of non-smokers.)

The **plan to quit** outcome was estimated solely among male smokers, as there were insufficient female youth smokers in our sample. Country of residence (living in Thailand) significantly increased the odds to plan to quit within 6 months in model 1 [OR=2.68, 95% CI (1.20, 5.99)], model 2 [OR=2.75, 95% CI (1.04, 7.30)], and model 3 [OR=2.96, 95% CI (1.19, 7.33)]. Therefore, male youth smokers in Thailand, where the graphic cigarette labeling policy was in place, were 2.7 to nearly 3 times more likely to plan to quit smoking than youth smokers in Malaysia, where no policy existed.

With regard to **smoking susceptibility,** country effects did not reach significance among male youth (non-smokers, never-smokers, or current smokers). Among female non- and never-smokers, residing in Thailand was associated with significantly lower odds of (any) smoking susceptibility in model 1 [OR=0.41, 95% CI (0.21, 0.79)], model 2 [OR=0.42, 95% CI (0.22, 0.77)], and model 3 [OR=0.39, 95% CI (0.18, 0.83)].

2.3.2. Label Salience and Cognition of Risk

Table 2.4 contains results for **label salience** and **cognition of risk.** Among male non-smokers and never-smokers, **label salience** was significantly associated with country of residence. The odds of reporting high (vs. low) label salience among male non-smokers was elevated by approximately 50% in Thailand, relative to Malaysia, in model 1 [OR=1.50, 95% CI (1.01, 2.24)], model 2 [OR=1.51, 95% CI (1.03, 2.21)], and model 3 [OR=1.68, 95% CI (2.13, 2.51)]. Similar, but stronger, results were found for male never-smokers {model 1 [OR=1.90, 95% CI (1.07, 3.38)], model 2 [OR=1.93, 95% CI (1.10, 3.38)], and model 3 [OR=2.04, 95% CI (1.16, 3.59)]}. We found no significant increase in odds of label salience among male smokers. The results were similar for female non-smokers and never-smokers. Thai female non- and never-smokers had approximately double the odds of high label salience of similar Malaysian females, in model 1 [OR=2.04, 95% CI (1.44, 2.89)], model 2 [OR=2.03, 95% CI (1.41, 2.91)], and model 3 [OR=1.74, 95% CI (1.24, 2.45)].

We found no significant association among male youth between **cognition of risk** and country of residence. Among female non- and never-smokers, participants living in Thailand had significantly higher odds of high cognition of risk (vs. low) than in Malaysia, in model 1 [OR=3.41, 95% CI (1.64, 7.11)], model 2 [OR=3.57, 95% CI (1.83, 6.95)], and model 3 [OR=2.87, 95% CI (1.35, 6.11)].

2.3.3. Smoking Behavior: Preliminary Results

Results of preliminary analysis of smoking behavior are presented in Table 2.5. We consider the results to be preliminary, or exploratory, because the models have limited statistical power, due to the somewhat small number of youth smokers and the further categorization of such smokers into outcome typologies. Given the data limitations, our models contain few adjustment variables, whose effects are presented in Table 2.5. In none of the behavioral models did graphic cigarette labeling (proxied by residing in Thailand) achieve statistical significance. Nevertheless, all coefficients were in the expected direction, and one outcome (quit attempt within the past year) had a strong trend toward statistical significance (OR=1.66, p=0.09).

2.4. Discussion

In this study, we used a quasi-experimental design to investigate the association between graphic cigarette labeling and smoking outcomes among Southeast Asian youth. More specifically, we examined how residing in Thailand, a country with a graphic warning policy, rather than residing in a Malaysia, a neighboring country without such a policy during the study frame, was related to numerous measures of

smoking, including intention, processing and cognition, and actual behavior. The results of genderstratified multivariate regression models indicated that living in Thailand (vs. Malaysia) was associated with: lower intention (plan) to smoke among male current smokers and female non-smokers and neversmokers; higher intention to quit among male smokers; reduced susceptibility to smoking among female non- and never-smokers; higher label saliency among both male and female non- and never-smokers; and higher cognition of risk among female non- and never-smokers. Although our analyses did not reveal significant associations between graphic warning labels and actual smoking behavior, we should make clear that those analyses were constrained by low statistical power, and should thus be interpreted as purely exploratory. Our findings align with those of some earlier research on the adult response in Southeast Asia, although differences in study frame, design, stratification, and models of smoking preclude direct comparison [22, 71, 105].

Whereas potential mechanisms for our results are not explored in this study, reasoned speculation may have some value in the consideration of our findings. For example, reductions in

smoking intentions among smokers could conceivably be motivated by short-term health effects. Smoking impairs young people's physical fitness, in terms of both performance and endurance—even among trained youth athletes [89]. Furthermore, teenage smokers suffer from shortness of breath almost three times as often as teens who do not smoke, and produce phlegm more than twice as often as teens who do not smoke [117]. Quite unrelated to adverse health, social stigma—resulting from societal, cultural, or religious norms—may also engage in the causal pathway. 'Social denormalization,' a process that seeks 'to push tobacco out of the charmed circle of normal desirable practice to being an abnormal practice' [118], is widely regarded as essential to successful policy outcomes.

Indeed, the influence of several social factors is revealed by our analyses—albeit as direct effects, rather than as mediators. Independent effects of covariates on smoking intention and susceptibility are presented in Tables 2.6.a--2.6.h.; label saliency and risk cognition in Tables 2.7.a.-2.7.h.; and smoking behavior in Tables 2.8.a.—2.8.e. *Peer smoking* was significantly associated with several outcomes: plan to smoke among male non-smokers, female non- and never-smokers; smoking susceptibility among male non-smokers and never-smokers; and label salience among male nonsmokers. *Smoking at home* was associated with plan to quit among male smokers and label salience among male never-smokers. *Society disapproves of smoking* was associated with plan to quit among male smokers.

This investigation builds on existing research in three notable ways. First, the use of 3 years of data allows us to circumvent the undue influence of extraneous policy events, and generate sufficient person-wave observations to analyze gender strata. Second, to our knowledge, this is the first study to examine the post-implementation youth response to graphic warning labels in Southeast Asia. Third, our quasi-experimental design is a rigorous approach, high in both internal and external validity [113].

There are, nevertheless, limitations that should be noted. First, our smoking measures are selfreported. Therefore, although research has affirmed the reliability and validity of measuring tobacco use through self-report methods [119], our measures may be prone to downward bias, and as a result, understate true tobacco use and intention to smoke. Second, our study lacks measures that may capture the mechanism through which the graphic warning labels affect smoking behaviors and behavioral intention. A similar study conducted among adults [71] found that graphic warnings not only had a significant impact on salience (versus text-only labels), but also on cognitive and behavioral reactions.

Taken together with experimental evidence that has consistently shown the sustained effect of graphic warning labels [120], this would suggest that the labels effect behavioral change directly, and not solely through the novelty of design. Third, our findings may be confounded by peripheral anti-smoking campaigns in Thailand during the study frame. Specifically, a major campaigned aimed at educating the public about the harm of secondhand smoke and passive smoking was launched just prior to wave 2 data collection (from May to June 2006). Even so, as the advertising campaign was not focused on the direct harm of primary cigarette consumption, the potential for bias resulting from confounding is likely minimal. Fourth, Malaysia began to roll-out a graphic warning label policy just prior to wave 4 data collection (which encompasses the follow-up period of wave-pair 3). It is possible that this may have introduced some bias, though it is unlikely the policy would have been rolled out at the time of data collection. Fifth, our study does not account for attrition, which was higher in the Malaysian sample than in the Thai sample, although tests of differential drop-out were not significant. In any case, future studies should apply appropriate methods to account for study attrition. Sixth, and finally, this study utilizes country of residence as a proxy for the warning label policy, but does not measure exposure directly.

Taken together, these findings support the implementation of graphic cigarette warning labels in Southeast Asia by reducing youth smoking intention and susceptibility to smoking, and increasing label saliency and cognition of risk. Southeast Asia is home to approximately 600 million smokers, representing a large majority of global tobacco burden. Most smokers begin at early stage of life and persist through adulthood. Malaysia alone has about 5 million smokers, 20% of whom are younger than 18 years old [121]. As such, understanding the impact of graphic cigarette warning labels as a potentially cost-effective and wide-reaching tobacco control policy is critical to preventing initiation and promoting cessation among youth in this vulnerable region. Continued research is needed to prevent the uptake of smoking and ultimately reduce tobacco-related morbidity and mortality, particularly in the face of the continuing influence of the tobacco industry [122, 123].

Chapter 3. Measuring the Effect of Warning Label Risk Cognition on Youth Smoking Intention and Behavioral Outcomes in Malaysia and Thailand: Results from International Tobacco Control Project

3.1. Introduction

It is estimated that nearly 80% of the more than one billion smokers worldwide live in low- and middle-income countries [79, 124, 125], with approximately 500 million smokers living in Asia alone [126]. Projections suggest that the number of smokers will increase significantly over the coming decades, as the tobacco industry shifts its markets to this region in response to the shrinking markets in the developed Western countries [127-129]. Whereas smoking has declined in developed countries as a result of extensive tobacco control efforts, including taxation, anti-smoking advertisements, media campaigns, and warning labels on cigarette packs [130], there has been less progress toward reducing smoking in developing countries, with some developing nations' showing increases in tobacco production and use [130]. If current smoking trends continue, estimates suggest that tobacco use will be attributable for roughly 10 million deaths each year by 2020; 70 percent of these deaths will take place in developing countries [130]. As such, there is an urgent need for more research to guide support tobacco control efforts in this region. Achieving greater progress in tobacco control may require focusing on strategies that are less expensive to implement and are thus more feasible for countries with fewer resources.

The World Health Organization (WHO) Framework Convention on Tobacco Control (FCTC) obligates the implementation of broad comprehensive tobacco control policies, which include the placement of rotating health warnings on tobacco packaging. Warnings must minimally cover 30% of tobacco packaging, but ideally cover more than 50% of the front and back of cigarette packages. Strong health warnings on cigarette packaging are a cost-effective educational strategy, as the only cost is that of implementing the policy [124]. Warning labels can be particularly effective as smokers are potentially exposed to the messages every time they wish to buy or smoke a cigarettes [81]. Warning labels have been shown to increase smoking-related health knowledge [131, 132] and cognitive processing [99] which are positively associated with quit intentions [17]. This article examines whether *graphic* cigarette warning labels effectively reduce smoking intentions, smoking susceptibility, and smoking behaviors among youth in two Southeast Asian countries: Malaysia and Thailand.

3.1.1. History of Tobacco Policies in Malaysia and Thailand

Although tobacco use is universal, social norms and cultural values shape people's smokingrelated attitudes, beliefs, and behavior [133, 134]. While Malaysia and Thailand are both Southeast Asian countries, they are culturally quite different. Thailand is dominated by Buddhist Thais whereas Malaysia is more multi-cultural, dominated by Muslim Malays, but with large minorities of Chinese and Indians.

Differences also exist in the two countries' historical approach to the tobacco epidemic [135]. Thailand is a leader in fighting the tobacco epidemic in the region, and has, for several years, been compliant with most requirements of the World Health Organization Framework Convention on Tobacco Control. Thailand was also one of the first countries to introduce comprehensive *policies* including bans on cigarette advertisements, bans on smoking in most public places, and bans on cigarette buying by Thai adolescents less than 18 years of age. The Thai government moreover introduced requirements in March 2005 for all cigarette packs to include graphic images that depict the ill effects of tobacco on health. With regard to smoking prevalence, a total of 11.7% of Thai youth (aged 14 years and below) reported smoking cigarettes in 2009. Large gender disparities, however, exist among smokers, with 20.1% of boys and 3.8% of girls reporting smoking [81].

In contrast, Malaysia has historically implemented few comprehensive tobacco control *policies*. Nevertheless, the Malaysian government launched a comprehensive national anti-smoking media *campaign* called *Tak Nak* (Say No) in February 2004, a year before our baseline survey. The objective of *Tak Nak* campaign was to reduce the number of smokers, particularly among adolescents, by providing them with accurate information to increase their awareness of, and knowledge about, the danger of smoking through posters, billboards, magazines and newspapers, radio, and television air time [136]. More recently, Malaysia has made significant strides in tobacco control *policy* including the implementation of graphic warning labels in January 2009. Despite recent efforts, smoking prevalence among Malaysian youth remains high. The 2009 Global Youth Tobacco Survey found that 19.5% of 13 to 15-year-olds use some form of tobacco products with 18.2% smoking cigarettes and 9.5% using other tobacco products. Gender disparities found among Thai youth are also apparent in Malaysia; among the

18.2% of Malaysian youth who smoked cigarettes in 2009, 30.9% of boys and 5.3% of girls reported being current smokers [81]. Findings from a recent population-based study indicate that among Thai and Malaysian youth not classified as smokers, approximately 11% (18% males and 3.4% females) and 12% (21% males and 2.6% females) are still experimenting with smoking, respectively [83].

3.1.2. Female Youth Smoking

Although smoking prevalence among Asian women in this region is typically low [136-138], some limited data suggest that smoking may be on the rise among young women [90, 91, 137]. The increased smoking among women could reflect either the shift towards modernization and emancipation of women in this region or the specific targeting of women by the tobacco industry as a huge untapped market for its products, or both [136, 137, 139]. A study using adolescent data from the first wave of the International Tobacco Control Southeast Asia (ITC-SEA) survey showed that female adolescents were less likely to hold positive aesthetic and social acceptability beliefs about smoking compared with their male counterparts, that Thai adolescents were more likely to endorse these beliefs, and that these beliefs were strongly predictive of smoking susceptibility [91]. Past research conducted mainly in Western developed countries suggests that the implementation of anti-smoking campaigns and advertisements may prevent smoking uptake among adolescents [127]. Specifically, previous studies have found that antismoking campaigns can have a significantly positive effect on the public's health knowledge which, in turn, may reduce smoking uptake [128].

3.1.3. Graphic Cigarette Warning Labels

According to the Southeast Asia Tobacco Control Alliance (SEATCA), while many tobacco users generally know that tobacco use is harmful, research has shown that most are unaware of the true risks, even in countries in which there has been a great deal of publicity about the health hazards of tobacco [140].

Adolescents, in particular, do not accurately understand the risks associated with smoking. Although youth "know" that smoking causes lung cancer, they demonstrate a lack of understanding of the magnitude of harm smoking causes [141-146]. For example, youth who smoke believe that

smokingrelated negative consequences are less likely to occur compared with youths who do not smoke [141,

143]. Youth also underestimate the extent to which smoking can shorten one's lifespan [142]. Moreover, adolescents incorrectly believe that health risks can be mitigated by altering their smoking behaviors, such as smoking light cigarettes instead of regular cigarettes [147]. The empirical literature strongly demonstrates that youth consistently misperceive the harmful and addictive nature of smoking [144, 148].

Even describing adolescent smoking initiation as a "decision" may be inappropriate especially because it is questionable as to whether youth are capable of being "fully or adequately" informed decision-makers [146, 149].

Health warning labels on cigarette and other tobacco product packages as well as all marketing materials, help inform consumers of the dangers of smoking, are an important component of national health education programs, and do not cost the government money to implement [150]. Health warning labels must include rotating messages in the principal languages of the country of implementation, and may include graphic images of the health effects associated with smoking.

Among adults, there is substantial evidence favoring the effectiveness of graphic health warnings [14, 20, 92-99], specifically with regard to intentions to quit, thoughts about health risks, decreased smoking prevalence, and cessation behavior [92, 100, 101]. Canada was the first country to require color graphic cigarette warnings, introducing them in 2000. Canadian research has demonstrated that graphic cigarette warnings are an effective way of communicating the health impacts of smoking [17, 20, 93, 94]. There is evidence that graphic warning labels significantly increase salience (reading and noticing); cognitive processing (i.e., thoughts of harm and quitting); and the behavioral response of forgoing cigarettes [14]. Cognitive processing reflects the extent that information is attended to and elaborated upon, and is suggested to be an important determinant of attitude formation in response to new information [94]. In studies of adult smokers, reading, thinking about, and discussing warning labels are used as indicators of cognitive processing [94, 99, 151]. A study by Hammond et al. found that in-depth processing of the warnings was predictive of making some attempt at cessation over the following three months [94]. Another study by Hammond et al. [36] found that approximately 20% of smokers they

surveyed reported smoking less because of the graphic warning labels. They also found that those who reported more negative emotion in response to the warnings were more likely to have quit or reduced smoking at 3 months follow-up.

Studies have shown that large graphic warning labels on cigarette packages are an important source of health information for smokers and non-smokers [37]. Exposure to graphic labels has been shown to reduce cigarette packet appeal [26], increase health knowledge, awareness and perception of risks associated with smoking [13-15, 17, 20, 94, 95, 100, 102], strengthen intentions to quit [94], encourage quit attempts [13, 20, 26, 100, 102], increase use of quitlines [95], prevent relapse [103], discourage smoking initiation [26, 100, 102] and decrease the odds of being a smoker [20, 101]. Additionally, there is evidence to support a greater cognitive impact of graphic warning labels on smokers with low-educational attainment [16] due to the visual modality of risk communication. As such, we hypothesize that the same may hold true for youth who inherently have a lower level of education than their adult counterparts.

Previous research has been conducted to test mediational models to determine the pathway through which warning labels might impact smoking behavior. Borland, Yong, Wilson, et al. (2009) [14] theorized that warning labels influence individuals by first influencing factors that are most proximal to the policy itself, such as noticing and reading the warning labels, and, as a result, act to influence the extent to which people think about the harms of smoking, which in turn raise their smoking-related health concerns, leading them to forgo smoking [152]. Yong et al. determined that, among smokers, warning labels stimulated thoughts about the risks of smoking (cognition of risk), which raised smoking-related health concerns, ultimately leading to stronger intention to quit and quitting behaviors [152]. The overall framework of the ITC model is that policies have immediate proximal impacts, which subsequently affect more general mediators of smoking behavior [11].

Although the majority of research on graphic cigarette warning labels has shown the policy to be effective, some argue that graphic labels may elicit avoidance, defensiveness, and denial. Ruiter and Kok [28, 29] argued that the evidence in support of the policy is sparse and unconvincing, and find flaws in the current research. Because graphic warnings are more fear-evoking than text-only warnings [153], smokers might employ defensive psychological mechanisms to protect themselves. Erceg-Hurn and

Steed [154] found higher reactance among smokers presented with graphic warnings as compared to the text-only warnings. That is, participants exposed to the graphic warnings felt more irritated, angry, annoyed and aggravated with the warnings than their text-only counterparts [155]. Furthermore, there is some evidence that graphic warnings incite defensiveness in response to fear-arousing information [28, 30, 31]. Experimental research on the effectiveness of graphic warning labels has shown that smokers defended themselves against the fear-inducing content, as they decreased their smoking-related risk perceptions compared to smokers who were not exposed to graphic warning labels [156, 157]. Such maladaptive defensive mechanisms might be the result of cognitive dissonance [155, 158].

3.1.4. Youth Smoking

Leventhal and Cleary [159] originally described smoking as a complex behavior that evolves through several stages. Smoking in adolescence is commonly conceptualized as progressing through a sequence of developmental phases characterized by varying smoking frequency and intensity [160], often culminating in nicotine dependence [161]. Basic definitions of smoking have been summarized as preparation, initial trying, experimentation, regular use, and addictive use [162, 163].

Many factors are implicated in the prevalence of tobacco use in Southeast Asia. Among youth smokers, a triad of family, environment, and individual factors synergistically act to motivate adolescents to smoke. Documented factors include experimentation and peer pressure, easy access and/or lack of restrictive laws, family, smoking, cultural norms, stress and psychological factors, smoking within school environments, and involvement with other high-risk behaviors [121]. In developing countries, such as Malaysia, curiosity, peer pressure, and feeling more matured have been shown to be the key factors responsible for initiation of smoking among youth [164, 165]. In Thailand, significant predisposing factors for adolescent smoking have been shown to be having close friends smoking and having smoking siblings [166, 167]. Other studies have also correlated adolescent smoking with parental smoking status [168, 169]. A study conducted among Indonesian youth found that ignorance of the health risks associated with smoking appears to be the significant determinant of smoking among adolescents, where a majority of the adolescents are unaware of the health risk of smoking whereas others believed health effects will only manifest if cigarettes are smoked for a certain period of time [170].

Research has shown that smokers who report seeing graphic health warnings reported more positive cognitions about smoking than smokers who saw the text-only warnings [155]. Because pack warnings have the capacity to be seen many times per day, they only need to be attended to on a minority of occasions to have effects. Studies have consistently found that reported frequency of avoiding warnings is positively associated with cognitive and behavioral responses that predict subsequent quitting activity [14, 71, 120].

Research on determinants of risk appraisal reveals that affective reactions are powerful sources of information [171, 172]. Warning images that evoke affective reactions to smoking, such as worry about the personal health cost of the habit, should engage the use of this affect heuristic to influence evaluations of the objective risks of smoking [171, 172] and elicit thoughts of smoking abstinence, a reduction in intensity of smoking, and quitting [173, 174]. However, such effects are predicted to be mediated rather than direct. That is, their influence on risk perceptions and beliefs about the hazards of smoking will depend on proximal emotional responses that vary across smokers.

While there have been several studies investigating the effectiveness of graphic cigarette warning label policies among adults in Canada, Australia, and other Western countries, there are few studies conducted in developing countries. Studies on the policy's effectiveness among youth are even more limited, and have mainly been conducted in experimental settings. The goal of our research is therefore to assess the effect of graphic warning labels on youth smoking intention, susceptibility to smoking, and smoking behavior. Our primary predictor variable, risk cognition, serves as a proxy for frequency of exposure, due to the potential correlation between smoking status and exposure to warning labels which may contaminate our analyses of smoking outcomes (e.g., a high intensity smoker will likely have a higher frequency of exposure to the warning labels, thus contaminating analysis of smoking intensity as an outcome). To our knowledge, this is the first study to utilize longitudinal data to conduct analyses of the effect of graphic warning labels on the youth behavioral response to graphic warning labels postimplementation of the graphic warning label policy, as well as the first to utilize data from Malaysia in the post-implementation period of the policy. We hypothesize that visual communication of risk may help

significantly increase the perceived harms of smoking, thus reducing intention to smoke, susceptibility to smoking, and ultimately, smoking behaviors.

3.2. Methods

3.2.1. Data Source

This study utilized nationally representative data from the International Tobacco Control South East Asia (ITC SEA) Project. Details on the conceptual framework of the ITC Project and its methodology have been published elsewhere [11, 12]. Briefly, the ITC SEA Survey is a cohort survey of nationally representative sample of youth and adults in Thailand and Malaysia. Eligible respondents originally included youth smokers and non-smokers (recruitment age 13-17 in Malaysia; age 13-19 in Thailand), adult smokers (age 18+) and adult non-smokers in Malaysia; adult non-smokers in Thailand were not recruited in any waves. As this study examines the youth response, adult subjects were excluded from our sample. Respondents were surveyed using face to-face and phone interviews, and were recruited from households using a stratified multistage sampling design. Survey fieldwork was conducted by trained interviewers in each of the two countries. Youth surveys were all self-reported; youth respondents completed a 30-minute self-administered (i.e., pencil and paper questionnaire). In order to minimize the effects of attrition, the sample was replenished to account for those lost to follow-up using the same sampling procedures at baseline. We limit our analyses to waves 2 through 5 for Thailand, and 4 and 5 for Malaysia to isolate post-policy implementation periods in each country.

In Figures 3.1 and 3.2 we present a timeline of tobacco policies and ITC survey data collection waves in Malaysia and Thailand, respectively. Wave 2 was conducted from August to September in Thailand, approximately 17-18 months after the introduction of graphic warning labels. Wave 3 was conducted from January to March 2008 in Thailand, approximately 11 months after the second round of graphic labels was implemented. Wave 4 was conducted from April to July 2011 in Thailand, approximately 26-29 months after the second round of labels was implemented, and from July to November 2009 in Malaysia approximately 1-5 months after the initial introduction of graphic warnings. Finally, wave 5 was conducted from February to April 2011 in Thailand, approximately 11 to 13 months

after the third round of graphic warnings was introduced, and from May 2011 to April 2012 in Malaysia, approximately 23 – 34 months after the introduction of graphic warning labels.

3.2.2. Measures

3.2.2.1. Primary Outcomes: Behavioral Intentions, Susceptibility, and Smoking Behavior

Behavioral Intentions: Plan to Smoke, Plan to Quit

Youth behavioral intentions were measured by the following variables: **plan to smoke** (measured among non-smokers and current smokers) and **plan to quit** within one month and within six months (among smokers). **Plan to smoke**, a binary variable, was assessed based on participant responses (fourpoint ordinal scale) to the following question: "At any time during the next year do you think you will smoke a cigarette?" The responses "probably yes" and "definitely yes" were coded 1 (i.e., plan to smoke in the following year); the remaining responses (probably no and definitely no) were coded 0 (i.e., no plan to smoke in the following year). **Plan to quit**, among smokers, was also a binary variable. It was assessed based on responses to the following survey question: "Which of the following describe your thoughts about quitting smoking?" Responses comprised: "I plan to quit in the next 30 days [1 month]"; "I plan to quit sometime in the next 6 months"; "I plan to quit, but not in the next 6 months"; and "I do not plan to quit at all". Respondents who reported planning to quit within the next 30 days or 6 months were coded 1; all those who reported not planning to quit were coded 0.

Smoking Susceptibility

Smoking susceptibility, among non-smokers (including former and never-smokers) and neversmokers (including participants who never smoked a cigarette) was a binary variable based on responses to two survey questions, each of whose responses were on a four-point ordinal scale (responses: definitely yes, probably yes, probably not, definitely not). The questions were: 1) "If one of your best friends were to offer you a cigarette, would you smoke it?" and 2) "At any time during the next year, do you think you will smoke a cigarette?" Participants who answered "definitely yes," "probably yes," and "probably not" to either question were coded 1, indicating susceptibility. Otherwise, respondents

were coded 0, suggesting non-susceptibility. The coding scheme for susceptibility was developed by Pierce et al [55], and has been utilized by similar research on youth smoking in Southeast Asia [56].

Smoking Behavior: Initiation, High-Intensity Smoking, Quit Attempt, Increased Intensity, Reduced Intensity

Smoking behavior was measured by 5 separate variables: **smoking initiation** (measured among non-smokers), **high intensity smoking** (among smokers), **quit attempt** (among smokers), **increased smoking intensity** (among smokers), and **reduced smoking intensity** (among smokers). **Smoking initiation**, a binary variable, took the value 1 where non-smokers at the baseline wave report smoking at follow-up. Smokers at follow-up included participants who reported smoking more than 100 cigarettes in their lifetimes and at least one cigarette in the last 30 days. **High intensity smoking**, among smokers, was a binary variable that took the value 1 if respondents reported smoking 10 or more cigarettes per day, and 0 if respondents reported smoking 9 or fewer cigarettes per day. **Quit attempt**, among baseline smokers, was a binary variable that took the value 1 if respondents indicated that they attempted to quit smoking in the last year (responses "in the last month" and "in the last year" combined). Changes in smoking intensity, among smokers, was measured by two binary variables: **increased intensity** and **reduced intensity.** Increased intensity was coded 1 if daily cigarette consumption at follow-up was greater than that at baseline, and 0 otherwise; reduced intensity was coded 1 if baseline consumption was greater than that at follow-up. Intensity at both waves was measured by ordinal, categorical, variables.

3.2.2.2. Independent Variable of Interest: Label Risk Cognition (Frequency of Exposure)

To assess the effect of the graphic warning label policy on smoking behavior, we utilized a measure of cognition of risk, measured by the survey item: "To what extent, if at all, have the health warnings made you think about the health risks of smoking?" Respondents who answered "a lot" were coded 1, indicating high cognition. Participants who answered "a little" or "not at all" were coded 0.

We also tested a variant of this measure. In the alternative measurement, participants who responded "a little" or "a lot" were coded as 1, indicating general cognition of risk; and those who responded "not at all" were coded 0, indicating no cognition of risk. However, due to the small number of respondents in the "no cognition" category, our models did not converge. Moreover, as we had originally

intended to study the effect of frequency of exposure to the graphic warning labels, we fitted models in which our outcome variable captured label saliency (notice), where our measure was the number of times in in the last month participants noticed health warnings on cigarette packages ("never," "once in a while," "often," and "very often"). Contrary to our expectations, the results of these models suggested a positive association between number of cigarettes smoked and frequency of exposure to graphic warning labels. We hypothesize that such a perverse effect arises from the conflation of the dependent and independent variables. (In other words, label saliency (notice), or exposure to graphic warning labels, among highintensity smokers occurs *via* the intensity of their consumption.) As a result, a tautology ensues, which precluded our use of the intended exposure variable, and motivated our search for a substitute measure.

3.2.2.3. Control Variables

The potential set of basic control variables comprise gender (female=1), age (proxied by being of legal smoking age follow-up=1), religion (3 dummy variables: Islam, Buddhism, and other (referent)), ethnicity (majority group vs. minor group (referent)), and urban/rural status (rural=referent). Ethnic minority status and urban/rural status were obtained from the household enumeration, which was completed by an adult informant. Religion and ethnicity were ultimately omitted from GEE analyses, as they were highly correlated with country of residence, as participants from Malaysia are primarily Islamic and Malay, and participants from Thailand predominantly Buddhist and Thai. We also controlled for cohort (the wave in which participants were first recruited into the ITC Project) and wave-pair, which accounts for secular changes.

3.2.2.4. Additional Covariates

A set of additional control variables accounts for cultural/attitudinal, social/normative, and intrapersonal factors. Such factors, derived from the Theory of Triadic Influence (TTI) [58, 59], have been shown to predict adolescent smoking behavior in previous research on youth smoking and other substance abuse [60-64]. Cultural/attitudinal variables encompass the demographic variables previously outlined. Social/normative variables included: **peer smoking, smoking at home, and perceived**

societal norms. **Peer smoking** was assessed by responses to the question: "Of the five closest friends that you spend time with on a regular basis, how many of them are smokers?" Responses 1 through 4 were dummy coded; 0 friends was the referent category. **[No] smoking at home** was measured by the survey item: "During the past 7 days (one week), how often have people smoked inside your home while you were there?" Responses comprised: "never," "sometimes," and "often." Respondents who answered "never" were coded 1; those who offered "sometimes" or "often" were coded 0 (referent). A measure of **perceived societal norms** was constructed based upon level of agreement with the statement: "Society disapproves of smoking." Responses, which were dummy coded, comprised: "agree," "in-between" and "disagree" (referent).

Intrapersonal factors included: **self-esteem, rebelliousness, and future discounting**. **Selfesteem** was a binary variable assessed by the survey item: "Choose one statement below that best describes you in the past two weeks, including today." Respondents who answered "I like myself" were coded 1, indicating high self-esteem. Respondents who answered "I hate myself" or "I do not like myself" were coded 0, suggesting low self-esteem (referent). A binary measure of **rebellion** was assessed by the survey item: "I do things my parents would not want me to do." Respondents who answered "often" were coded 1, indicating rebelliousness. Respondents who answered: "never" or "sometimes" were coded 0, indicating little or no rebelliousness (referent). **Future discounting** was assessed by level of agreement to the statement: "I spend a lot of time thinking about how what I do today will affect my life in the future." Participants who responded "agree" were coded 1, indicating a low discount rate. Respondents who answered "in-between" or "disagree" were coded 0, indicating a high discount rate (referent).

3.2.3. Statistical Analysis

3.2.3.1. Descriptive Analysis

Univariate statistics were used to describe the sample. Results are stratified by country (Malaysia and Thailand), as well as smoke status (non-smokers and smokers). We present frequencies as well as sample proportions displayed as column percentages.

3.2.3.2. Inferential Analysis

We used data from seven years (2006-2012) of the ITC-SEA. The data were arranged in three wave-pairs for Thailand and one wave-pair for Malaysia, in which we combined contiguous baseline and follow-up data.

Wave-pair 1	**Wave-pair 2**	**Wave-pair 3**	**Wave-pair 4**
Wave 1 + Wave 2	Wave 2 + Wave 3	Wave 3 + Wave 4	Wave 4 + Wave 5
TH: Jan 2005 – Sept 2006	TH: Aug 2006 – Mar 2008	TH: Jan 2008 – July 2009	TH: Apr 2009 – Apr 2011
MY: Jan 2005 – June 2007	MY: Aug 2006 – Sept 2008	MY: Feb 2008 – Nov 2009	MY: Jul 2009 – Apr 2012

The 2006-2012 period in Thailand, and 2009-2012 period in Malaysia, reflect a policy environment in which both countries had enacted graphic cigarette warning labels (i.e., existed in post-policy period).

Equation (1) depicts the relationship between our smoking outcomes and cognition of risk.

$$\text{Logit}(P(\text{SMOKING OUTCOME}_{it})) = \beta_0 + \beta_1 \bullet \text{COGNITION OF RISK}_i + \beta_x \bullet X_{i(t-1)} \quad (1)$$

In our model, SMOKING OUTCOMES, which were measured at follow-up (time t), are a function of COGNITION OF RISK (the proxy for frequency of exposure to the graphic warning labels), and a vector of covariates (X), which were lagged to the baseline (t-1) of each data wave-pair. β_0 is the regression constant. We estimated the models with the Generalized Estimating Equations (GEE) technique, which generates population-averaged (marginal) effects of graphic cigarette warning labels on smoking outcomes. GEE is preferable to other techniques (e.g., fixed effects regression) for several major reasons. First, it corrects for intra-subject correlation that arises from repeated-measures data. Second, it estimates population-averaged coefficients directly from observed data without restrictive assumptions about heterogeneity across individuals in the parameters [116]. Third, it accommodates dependent variables of various distributions (e.g., linear, logit, count, etc.) And finally, it permits the overt estimation of regression parameters on time-independent covariates, whose effects on the outcomes may be of interest to the investigator or policymaker.

We fitted separate, gender-stratified, models of the effect of graphic cigarette labeling for each smoking outcome. Most models were country-specific, however, we also estimated a combined-country model in which we controlled for country (Malaysia=referent). In accordance with the Theory of Triadic Influence (TTI), the models were built in a partially hierarchical fashion, wherein we added a theoretically linked set of covariates at each stage in the process, while removing the set that was added in the

previous step. The first, benchmark, model specification included the primary predictor variable, cognition of risk (the proxy for frequency of exposure to the graphic warning labels) (High Cognition=1; Low Cognition=referent) and demographic controls (cultural/attitudinal factors); the second specification added social/normative variables to the initial specification; the third, and final, specification added intrapersonal factors to the first specification, but omitted the social/normative set. All models controlled for wave-pair (i.e., time) and cohort. Only crude, unadjusted models, were fitted for smoking behavior, as an insufficient number of youth smokers precluded model convergence when covariates were controlled. Smoking behavior models were, moreover, estimated only among male youth, due to the low prevalence of smoking among female youth in both Thailand and Malaysia. The decision to stratify is based on documented disparities in smoking across men and women [8, 81, 82]; this decision was further supported by the results of tests of sex differences in our models. In pre-estimation testing, we observed statistically significant ($p>0.0001$) coefficients on country x gender interactions in all model specifications.

Our analyses were conducted using SAS-Callable SUDAAN version 11.0.1 to account for the multistage sampling design and oversampling used in the ITC-SEA Project and the longitudinal nature of the data. Analyses were conducted using unweighted and weighted data for all models, with no significant differences observed between weighted and unweighted analyses. Results are presented for weighted analyses, with standard errors and model coefficients adjusted accordingly. As all outcomes are binary, we generate odds ratios and 95% confidence intervals. The QIC (Quasi-likelihood under the Independence model Criterion) statistic was used for comparing models fit with likelihood-based methods among otherwise equally suitable structures.

3.3. Results

Table 3.1 contains summary statistics, by smoke status, for the country-stratified sample. Approximately 6.81% of the Malaysian sample and 12.41% of the Thai sample reported being current smokers at the final wave of the study frame. With regard to our primary predictor variable, cognition of risk, the proportion of participants with a high cognition of risk was higher among non-smokers (51.29%) versus smokers (35.59%) in Thailand. The proportion of participants with a high cognition of risk was comparable among non-smokers (65.96%) and smokers (65.52%) in Malaysia. However, it should be

noted that since there was only one post-implementation wave-pair utilized for Malaysia, the sample size is small (n=438) relative to Thailand (n=1958), for which three wave-pairs were analyzed. The number of smokers within Malaysia is, therefore, extremely small (n=30), thus limiting analyses among Malaysian youth smokers. Other relevant information may be obtained from Table 3.1.

3.3.1. Format of Multivariable Results/Model Recapitulation

In the following sections, we present gender-stratified results of analyses that investigated the association between cognition of risk (a lot vs. little or no) and our smoking outcomes. The models were estimated separately for participants who indicated being current smokers, non-smokers, and neversmokers. Once more, three models of behavioral intention and susceptibility to smoking were modeled using the Theory of Triadic Influence (TTI) as a framework [58, 59]. Model 1 adjusted for wave-pair, urban/rural status, and being of legal smoking age (cultural/attitudinal). (We should note that country was controlled at this level in the set of models that combine Thailand and Malaysia.) Model 2 built upon model 1 by additionally adjusting for behavioral factors: peer influence, parental influence, and perceived societal norms (social/normative). Model 3 also built upon model 1 by adding adjustment variables for personal factors: self-esteem, rebelliousness, and discount rate (intrapersonal). The majority of models are limited to one, or the other, country. We do, however, combine data from Malaysia and Thailand, in one series of models. Doing so achieves two goals: we increase statistical power to detect differences in our outcomes by cognition of risk categories; and observe the collective effect of graphic warning labels on youth in two Southeast Asian countries.

3.3.2. Plan to Smoke

Outcomes for plan to smoke among Thai-only youth are presented in Table 3.2, and for both Thai and Malaysian youth (collectively, Southeast Asian youth) in Table 3.4. The results of analyses that investigated the association between plan to smoke and cognition of risk were not significant among Thai youth, nor among Southeast Asian youth, generally (Thai and Malaysian youth combined). In neither males nor females, did we observe a statistically significant relationship. Further, the limited number of

never-smokers (n=311) in Malaysia precluded analyses for 'plan to smoke' among this sub-population in our combined analysis of Southeast Asian youth.

3.3.3. Plan to Quit

Outcomes for plan to quit among Thai-only youth are presented in Table 3.2, and for both Thai and Malaysian youth (collectively, Southeast Asian youth) in Table 3.4. The results of analyses that investigated the association between plan to quit and risk cognition were not significant among Thai male youth, the only sub-population for which we were able to conduct analyses, due to limited number of female youth smokers in Thailand, and male or female youth smokers in Malaysia.

3.3.4. Smoking Susceptibility

Outcomes for smoking susceptibility among Thai-only youth are presented in Table 3.2, and for both Thai and Malaysian youth (collectively, Southeast Asian youth) in Table 3.4. Among Thai *male nonsmokers,* the odds of any susceptibility to smoking were approximately 27-28% lower among participants with high cognition of risk ("a lot") than those with low cognition of risk ("a little" or "not at all"). This result

was robust across the 3 model specifications {model 1 (OR=0.72, 95% CI [0.59, 0.88]), model 2 (OR=0.73, 95% CI [0.58, 0.93]), and model 3 (OR=0.72, 95% CI [0.58, 0.88])}. The association between susceptibility to smoking and cognition of risk was not statistically significant among Thai females. The association was also not statistically significant among males or females in the analyses that combined Thai and Malaysian youth, controlling for country.

3.3.5. Behavioral Outcomes

3.3.4.1. Smoking Initiation

Behavioral outcomes for male youth in Thailand are presented in Table 3.4. Our results indicate that the odds of **smoking initiation** were 62-63% lower among participants with high cognition of risk than those with low cognition of risk. This result was robust across the 3 model specifications: {model 1 (OR=0.37, 95% CI [0.11, 0.41]), model 2 (OR=0.37, 95% CI [0.26, 0.54]), and model 3 (OR=0.38, 95% CI

[0.26, 0.56])}. The small number of smokers within Malaysia (n=30) precluded the analysis of behavioral outcomes among Malaysian youth smokers. Not shown, however, are the results of regression analyses of smoking initiation (assessed among baseline non-smokers in Malaysia), controlling for wave-pair, cohort, urban/rural status, and legal smoking age. We found that, among Malaysian male youth smokers, the odds of smoking initiation were reduced by 40% among participants with high cognition of risk than those with low cognition of risk (OR=0.60, p=0.0025).

3.3.4.2. High Intensity Smoking

The odds of being a **high intensity smoker** (>10 cigs) was associated with high cognition of risk across model 1 (OR=3.62, 95% CI [1.33, 9.79]) and model 3 (OR=3.28, 95% CI [1.10, 9.78]); model 2 did not converge.

3.3.4.3. Quit attempt

The odds of making a **quit attempt** within the past year were not significantly different for participants with high cognition versus those with low cognition.

3.3.4.4. Smoking Intensity

The **odds of increasing smoking intensity** between baseline and follow-up was associated with high (versus low) cognition of risk in model 1 (OR=2.89, 95% CI [1.31, 6.37]) and model 3 (OR=3.28, 95% CI [1.43, 7.54]); model 2 did not reach statistical significance. Participants with high cognition of risk had approximately three times the odds of increasing smoking intensity of those with low cognition of risk. The **odds of reducing smoking intensity** between baseline and follow-up waves were significantly higher among participants with high cognition or risk than those with low cognition of risk. This result was robust across the 3 model specifications {model 1 (OR=2.71, 95% CI [1.07, 6.85]), model 2 (OR=3.20, 95% CI [1.08, 8.23]), and model 3 (OR=3.47, 95% CI [1.07, 11.28])}.

3.4. Discussion

This study utilized a two-period follow-up design to examine the relationship between cognition of risk and smoking outcomes after the introduction of graphic cigarette warning labels in Thailand and Malaysia. Our analyses explored associations between cognition of risk and two types of smoking responses: intentions and behavior. Consistent with the notion that high cognition of risk credibly proxies

consideration of the potential harm of smoking that is provoked by examining graphic warning labels, we found that high cognition of risk was associated with decreased odds of susceptibility to smoking, decreased odds of smoking initiation, and increased odds of a reduction in smoking intensity among male youth. Inconsistent with this concept, however, we also found that high cognition of risk was associated with increased odds of being a high intensity smoker (>10 cigarettes/day) and increasing smoking intensity at follow-up among male smokers.

The unanticipated observed association between risk cognition and high intensity smoking and increased intensity may be due, in part, to reverse causality, as heavy smokers are more likely to have experienced smoking-related side effects, and are therefore more likely to have a higher cognition of the risks associated with smoking than non-smokers or lower intensity smokers. Prior research has found a causal relationship between active smoking and respiratory symptoms in children and adolescents, including coughing, phlegm, wheezing, and dyspnea [148]. Furthermore, parental, familial, and peer smoking are known risk factors for youth smoking [175-179], making it more likely that youth smokers have family members and friends who are smokers, thus also increasing their secondhand exposure to the health effects of smoking through social observations. A less likely, albeit plausible, explanation is that there is in fact a "boomerang" effect among a sub-population of male youth smokers. Some previous researchers have documented that exposure to anti-smoking communications can have the unintended consequence of increasing smoking-related intentions [180], leading some to argue against graphic warning label policies [181]. However, the majority of research has failed to detect subgroups for which such boomerang effects can be anticipated [182].

Although not the focus of our study, several demographic and social variables merit note as significant correlates of smoking behavior. Living in Thailand, as compared to Malaysia, was associated with increased odds of *planning to smoke* and *smoking susceptibility* among male youth non-smokers in Southeast Asia. Such a country difference may suggest that the graphic labels may have been more effective in Malaysia than in Thailand. It is possible that the long history of anti-tobacco campaigns and policies in Thailand primed youth to the warning labels, while the novelty of the messages in Malaysia may have increased their impact and effectiveness among youth [13, 151]. In addition to country, time, measured by wave-pair dummies, was associated decreasing odds of *plan to quit* and *quit attempt*

among male smokers in Thailand. Nonetheless, without overt specification of the policy variable, it is unclear whether the observed effect represents a secular smoking trend, which is unrelated to the graphic cigarette labeling policy, or a decaying impact of the policy. In addition, *peer smoking* was associated with several outcomes among relevant subgroups, including *plan to smoke (increased odds), plan to quit (decreased odds), smoking susceptibility (increased odds), and smoking initiation (increased odds).*

Our study adds to the extant literature in the following ways. It is the first investigation of which we are aware to examine the effect of cognition of risk (provoked by graphic cigarette labeling), as an independent variable, in relation to youth smoking outcomes in Southeast Asia. It is moreover the first study of youth smoking in the *post*-policy implementation period in Malaysia. Although the Malaysian sample was too small to permit much statistical inference, we were nonetheless able to combine Malaysian data with Thai youth data to examine effects among Southeast Asian youth collectively. Our research also augments previous investigations of youth *behavioral intentions* by exploring actual smoking behavior. Furthermore, our use of theory-driven, tobacco-specific psychosocial control variables strengthens the design of our models. Lastly, our use of multiple wave-pairs allowed us to generate enough statistical power to stratify by gender, as well as to examine different classifications of smokers separately.

Results from Chapter 2, in which a quasi-experimental approach was utilized—with Malaysia representing the pre-policy period and Thailand representing the post-policy period—revealed significant country differences in smoking intention outcomes, suggesting that graphic warning labels positively influence youth smoking. This study expanded that research by uncovering an association between consideration of smoking labels (cognition of risk) and smoking. We should restate that the original aim of this study was to explore the relationship between smoking outcomes and frequency of exposure to graphic warning labels among Southeast Asian youth. However, as frequency of exposure is directly correlated with smoking behavior—more specifically, higher intensity smokers are more frequently exposed to warning labels than nonsmokers or lower intensity smokers—it was replaced by cognition of risk, a measure uncontaminated by the potential tautology. Previous research conducted among adult smokers supports our substitution of the key independent variable. One study indicated that health warning labels influence behavior primarily through their ability to stimulate thoughts about the risks of

smoking, which in turn help to raise smoking-related health concerns, which reduce intention to smoke [152].

Even so, several limitations should be noted. For example, although research has affirmed the reliability and validity of measuring smoking behaviors through self-report methods, our measure of tobacco use may be prone to downward bias, and therefore understate true smoking behavior [119]. However, measures were taken to reduce bias by having youth complete a written 30-minute selfadministered questionnaire, rather than submit responses via face-to-face or phone interviews. In addition, we do not account for the two rounds of new (refreshed) graphic warning labels introduced in Thailand over the course of our study period. Previous research has found that novelty of design may affect smoking outcomes, perhaps as much, or even more, than the content of the label message [13, 151]. We are also unable to isolate the effect of the graphic warning labels from the effects of peripheral tobacco control efforts that occurred over the course of our study period. Additionally, we do not account for the policy roll-out period, and cannot be certain that the Malaysian graphic warning labels were rolled out entirely before wave 4 of the survey, which was deployed only 1-5 months after the implementation of the policy. As such, more extensive post-implementation data are needed to better understand the longterm effects of the labels on Malaysian youth. Lastly, though our population was replenished at every wave, we do not account for dropout in our analyses. A weighted generalized estimating equation (GEE) approach is typically more appropriate for datasets prone to missing observations, as they extend the traditional GEE approach to better account for dropout, assuming data are missing at random [183].

It is imperative that tobacco control policies be studied in the context of developing countries, such as Thailand and Malaysia, where there still exists a high prevalence of smoking due to the shifting focus of the tobacco companies away from the Western world. Graphic cigarette warning labels appear to effectively reduce smoking initiation and smoking susceptibility among Thai and Malaysian youth nonsmokers, as well as decrease smoking intensity among smokers. Promoting effective modalities of risk communication, such as graphic warning labels, intended to educate and inform people about the dangers of tobacco use is on the forefront of the global public health agenda. Understanding and encouraging strategies aimed at preventing smoking initiation among youth is the most effective way to reduce tobacco-related morbidity and mortality in these populations.

Chapter 4. Investigation of the Impact of Graphic Cigarette Warning Label Salience on Adult Smoking Behaviors in Malaysia and Thailand and Moderating Effects of Loosies: Results from International Tobacco Control Project

4.1. Introduction

The development of effective tobacco control policies aimed at curbing smoking is a global health priority. The World Health Organization (WHO) Framework Convention on Tobacco Control (FCTC), which was adopted in 2005, has formalized global commitment to reducing smoking worldwide [184]. However, country-specific progress varies substantially, with a high prevalence of smoking and stagnating trends in many countries [185]. WHO estimates that approximately six million people worldwide die each year from causes attributed to smoking, with most of these deaths occurring in lowincome and middle-income countries [184, 186]. If current trends continue, tobacco-induced mortality will reach 8.3 million by 2030, with 80% of deaths in developing countries [187]. Smoking projections underscore the need for innovative tobacco control strategies to reverse trends and accelerate progress where smoking prevalence remains high.

Tobacco companies have spent decades and many millions of dollars creating advertising campaigns that have been found to be extraordinarily effective in creating, maintaining, and expanding their market. Cigarette advertising companies developed these techniques through careful research, much of which has utilized the findings and theoretical perspectives of social psychology and marketing [37]. As such, the development and expansion of public health policies aimed at reversing these trends is imperative. One such policy is the implementation of graphic cigarette warning labels which use images of the health effects of smoking to effectively communicate smoking-related risks.

4.1.1. Graphic Cigarette Warning Labels

Health warning labels on cigarette packs represent a low cost, educational policy aimed at decreasing tobacco consumption and subsequent mortality [92]. Over the past few decades, warning labels have become a popular method by which governments attempt to inform their citizens of the health consequences of smoking, although the nature of those health warnings varies considerably across countries [37]. Graphic warning labels have been shown to be more effective than text-only warnings [13,

120], especially in countries with low literacy or where several languages are spoken [13]. The FCTC obligates the implementation of broad comprehensive tobacco control policies, including the placement of rotating health warnings on tobacco packaging written in all principal languages. Warning labels should describe specific harmful effects of tobacco use on health and are suggested to cover at least 30%, but ideally at least 50%, of the package's external surface area [188, 189].

The basic assumption underlying the demand for health warnings cigarette packs is that people are not aware, or not fully aware, of the dangers of tobacco. Education on these dangers would, therefore, prevent initiation among non-smokers or lead smokers to quit or reduce smoking intensity. Indeed, although most people know that smoking is harmful in general, many tobacco users underrate the risk to which they are exposing themselves and others [17]. Furthermore, smokers tend to underestimate the range of illnesses associated with tobacco use [190]. This lack of knowledge is met by false beliefs that further undermine perceiving tobacco use as a health risk. Specific examples of include the assumption that ‘low-tar’ and ‘light’ cigarettes are less harmful [191] and that quitting smoking is easy since it is a ‘bad habit’ and not an addiction [192].

4.1.2. Effectiveness of Graphic Warning Labels among Adults

Among adult smokers, there is substantial evidence favoring the effectiveness of graphic health warnings as a tobacco control measure [14, 20, 92-101]. Previous research has found that large graphic warning labels on cigarette packages are an important source of health information for smokers and nonsmokers [37]. Exposure to graphic labels has been shown to reduce cigarette packet appeal [26], increase health knowledge, awareness and perception of risks associated with smoking [13-15, 17, 20, 94, 95, 100, 102], strengthen intention to quit [94], encourage quit attempts [13, 20, 26, 100, 102], increase use of quitlines [95], prevent relapse [103], discourage smoking initiation [26, 100, 102] and decrease the odds of being a smoker [20, 101]. The majority of research on the impact of graphic warning labels has been conducted in Western countries, the knowledge from which is not necessarily generalizable to developing countries, due to different socioeconomic conditions and cultural contexts and disparities in tobacco control policies and social acceptability of smoking [65, 193, 194]. Thus, there is a crucial need for research in these regions.

The limited evidence published in developing countries suggests the effectiveness of graphic warning labels is promising. An experimental study in China found that adult smokers were more likely to rate graphic warnings as more effective than text-only warnings in motivating smoking cessation and preventing smoking among youth [104]. Similarly, an experimental study conducted in Malaysia prior to the implementation of the graphic warning label policy suggested that graphic labels had a greater positive impact than text-only labels [22]. Other studies have supported the conclusion that graphic labels impact cognitive and behavioral reactions, as well as desire to quit [16, 105]. A study by Yong et al. (2013) found that, following the implementation of the graphic warning label policy in Thailand, smokers' salience, and cognitive and behavioral reactions increased markedly, with effects sustained at follow-up, as compared to Malaysian controls [71].

Although the majority of research has supported the effectiveness of graphic cigarette warnings in their goal of reducing smoking behavior, some researchers argue that graphic labels have no effect, or a potentially negative effect on smoking outcomes. Petersen and Lieder (2006) found no difference between the influence of text-only and graphic warning labels on perceived health risks, outcome expectations, self-efficacy expectations, and behavior [195]. Ruiter and Kok [28, 29] contend that the evidence in support of the policy is sparse and unconvincing, and find flaws in research design and methodology.

Some psychologists and social scientists argue that graphic labels may elicit avoidance, defensiveness, and denial. Smokers may even take measures to cover the cigarette packs or buy loose cigarettes ("loosies") to avoid exposure to warning labels. The graphic nature of the warnings is intended to evoke more fear than text-only warnings [153], which may cause smokers to employ defensive psychological mechanisms to protect themselves [28, 30, 31]. Erceg-Hurn and Steed [154] found that participants exposed to the graphic warnings felt more irritated, angry, annoyed and aggravated with the warnings than their text-only counterparts. Experimental research on the effectiveness of graphic warning labels has shown that smokers defended themselves against the fear-inducing content, as they decreased their smoking-related risk perceptions compared to smokers who were not exposed to graphic warning labels [156, 157]. Such mal-adaptive defensive mechanisms might be the result of cognitive dissonance [155, 158], the situation involving conflicting attitudes, beliefs, or behaviors. In the context of warning

labels, the theory of cognitive dissonance would predict that there might be a perceptual distortion of the cognitive element concerning the believability of the warning labels' statements of the harms of smoking [196].

The conflicting evidence on graphic warning label policies, as well as the lack of evidence from developing countries, underscores the need for additional research their impact on smoking outcomes. The goal of our research is to assess the effect of graphic cigarette warnings on adult smoking behavior in Thailand and Malaysia, specifically: high smoking intensity, reduced smoking intensity, plan to quit, quit attempts, and cessation. Our primary predictor variable, label saliency, serves as a proxy for frequency of exposure, due to the potential correlation between smoking status and exposure to warning labels, which may contaminate our analyses of smoking outcomes (e.g., a high intensity smoker will likely have a higher frequency of exposure to the warning labels, thus contaminating analysis of smoking intensity as an outcome).

Our study will address gaps in the research in the following ways. First, we utilize multiple waves of data spanning from 2006 to 2012, from the International Tobacco Control (ITC) Southeast Asia (SEA) Project. Second, our primary outcome variables, smoking intensity and cessation, are measures of behavioral *change*, which build upon many previous studies focusing on behavioral *intention*. Third, this is the first study of which we are aware to analyze post-policy implementation data on adults from Malaysia. Lastly, we utilize two different measures of label salience; the first compares *never* reading warning labels to *ever* reading warning labels. The second compares levels of frequency with which labels are read (*high* versus *low* frequency).

Our primary objective is to better understand the role of label salience in the context of graphic cigarette warning labels, and to determine if label salience is an effective predictor of smoking behavior. Furthermore, this issue is especially important in light of potential avoidance tactics such as buying single cigarettes or covering packs, which would seemingly inhibit exposure to graphic warning labels and thus hinder label salience. As such, we also explore purchasing loose cigarettes as a potential effect modifier of the association between label salience and smoking outcomes.

4.2 Methods

4.2.1. Data Source

This study utilized nationally representative data from the International Tobacco Control South East Asia (ITC SEA) Survey. Details on the conceptual framework of the ITC Survey and its methodology have been published elsewhere [11, 12]. Briefly, the ITC SEA Survey is a prospective, longitudinal, cohort survey of youth and adults in Thailand and Malaysia. Eligible respondents include youth smokers and non-smokers (recruitment age 13-17 in Malaysia; age 13-19 in Thailand), adult smokers (age 18+) and adult non-smokers in Malaysia; adult non-smokers in Thailand were not recruited in any waves. As this study examines the adult response, youth were excluded from the sample. Additionally, as outcomes included smoking intensity, quit attempts, and cessation, only adults classified as baseline smokers were included in our sample. A smoker is defined here as someone who has smoked at least 100 cigarettes in their lifetime and smokes at least weekly. As such, adult non-smokers (at baseline) were also excluded from analyses, though participants may be 'quitters' at follow-up. Respondents were surveyed using face to-face and phone interviews, and were recruited from households using a stratified multistage sampling design. Please see figures 4.1 and 4.2 for a timeline of tobacco policies and ITC survey data collection waves in Malaysia and Thailand, respectively.

We limit our analyses to waves 2 through 5 for Thailand, and 4 and 5 for Malaysia to isolate postpolicy implementation periods in each country. Data collection for wave 2 was conducted from August to September in Thailand, approximately 15-18 months after the introduction of graphic warning labels. Wave 3 was conducted from January to March 2008 in Thailand, approximately 11 months after the second round of graphic labels was implemented. Wave 4 was conducted from April to July 2011 in Thailand, approximately 26-29 months after the second round of labels was implemented, and from July to November 2009 in Malaysia approximately 1-5 months after the initial introduction of graphic warnings. Finally, wave 5 was conducted from February to April 2011 in Thailand, approximately 11 to 13 months after the third round of graphic warnings was introduced, and from May 2011 to April 2012 in Malaysia, approximately 23 – 34 months after the introduction of graphic warning labels.

4.2.2. Measures

4.2.2.1. Primary Outcome: Smoking Behavior

Smoking behavior was measured by 6 separate variables: **high smoking intensity** (15+ cigarettes per day)**, reduced smoke intensity**, **plan to quit within 6 months, quit attempts** (between baseline and follow-up waves), **cessation** (defined as not having smoked a cigarette in the past 30 days), and **quit because of label** (among those who quit between baseline and follow-up).

High smoking intensity, among smokers at follow-up, took the value 1 where participants reported smoking 15 or more cigarettes at follow-up. Respondents who reported smoking fewer than 15 cigarettes at follow-up were coded 0. Among smokers, change in **smoking intensity**, specifically 'reduced smoking intensity,' was assessed by the question, "Since we last talked to you, about one year ago, have you made any change in the amount you smoke?" If participants responded "yes," they answered the follow-up question, "What change did you make?" Responses included: "Quit smoking," "Reduce smoking," and "Increase smoking." **Reduced intensity** was coded 1 if participants responded "decreased intensity," and 0 otherwise (excluding those who were 'quit' at follow-up).

Plan to quit within 6 months was a binary variable measured among participants classified as smokers at follow-up. It was based on responses to the following survey question: "Which of the following describe your thoughts about quitting smoking?" Responses comprised: "I plan to quit in the next 30 days [1 month]"; "I plan to quit sometime in the next 6 months"; "I plan to quit, but not in the next 6 months"; and "I do not plan to quit at all". Respondents who reported planning to quit within the next 30 days or 6 months were coded 1; all those who reported not planning to quit within 6 months ('I plan to quit, but not in the next 6 months' or 'I do not plan to quit at all') were coded 0.

Quit attempt, measured among baseline smokers, was a binary variable based upon responses to the question, "Since we last talked to you, have you made any attempts to quit?" Quit attempt took the value 1 if respondents replied 'yes,' and 0 otherwise. **Cessation**, also measured among baseline smokers, was assessed by the question, "Since we last talked to you, about one year ago, have you made any change in the amount you smoke?" If participants responded "yes," they answered the followup

question, “What change did you make?” Responses included: “Quit smoking,” “Reduce smoking,” and “Increase smoking.” Cessation was coded 1 if participants responded “quit smoking,” and 0 otherwise.

Quit because of label was assessed by the question, “In the past 6 months, were you led to quit or stay quit by warning labels on cigarette packages?” Respondents who answered “very much” or “somewhat” were coded 1, all those who responded “not at all” were coded 0.

4.2.2.2. Independent Variable of Interest: Label Salience

To assess the effect of the graphic warning label policy on smoking behavior, we utilized a measure of label salience, known in this literature as “**reading**” labels. Label salience is measured by the survey item, “In the last month, how often, if at all, have you read or looked closely at the health warnings on cigarette packages?” The response options were “never,” “once in a while,” often,” and “very often.” We measure label salience in two ways: first, we assess the impact of *any* label salience (versus *no* label salience) by coding participants who responded “once in a while,” “often,” or “very often” as 1, and all those who responded “never” as 0. Second, we assess the effect of *high* versus *low* salience by coding participants were responded “often” or “very often” as 1, reflecting high salience, and all those who responded “once in a while” or “never” as 0, reflecting low salience.

Moreover, as we had originally intended to study the effect of frequency of exposure to the graphic warning labels, we fitted models in which our outcome variable captured label salience (**notice**), where our measure was the number of times in in the last month participants *noticed* health warnings on cigarette packages (“never,” “once in a while,” “often,” and “very often”). Contrary to our expectations, the results of these models suggested a positive association between number of cigarettes smoked and frequency of exposure to graphic warning labels. We hypothesize that such a perverse effect arises from the conflation of the dependent and independent variables. (In other words, label saliency (*notice*), or exposure to graphic warning labels, among high-intensity smokers occurs *via* the intensity of their consumption.) As a result, a tautology ensues, which precluded our use of the intended salience variable, and motivated our search for a substitute measure. Although subtle, the distinction between simply *noticing* the labels and *reading* the labels resolved the observed perverse effect.

4.2.2.3. Sociodemographic Variables

The potential set of basic control variables comprise gender (female=1), age group (4 dummy variables: 18-24 (referent), 25-39, 40-54, and 55 years and older), religion (3 dummy variables: Islam, Buddhism, and other (referent)), ethnicity (majority group vs. minor group (referent)), and urban/rural status (rural=referent). Ethnic minority status and urban/rural status were obtained from the household enumeration. Religion and ethnicity were ultimately omitted from GEE analyses, as they were highly correlated with country of residence, as participants from Malaysia are primarily Islamic and Malay, and participants from Thailand predominantly Buddhist and Thai.

We derived relative measures for education and income to standardize across countries using standards set by Li et al (2010) [65]. "Low" level of education (referent) was defined as receiving no schooling/lower elementary in Malaysia or no schooling/low elementary in Thailand; "moderate" education was defined as upper elementary to upper secondary in Malaysia or elementary to upper secondary in Thailand; "high" level of education was defined as postsecondary education (from pre-university to postgraduate degree). With regard to income, "low" income was defined as earning $\leq$10,000 ringgit in Malaysia (referent), $\leq$70 Baht in Thailand, annually; "moderate" income was defined as earning between 10,001 and 30,000 ringgit in Malaysia, 70,001 through 195,749 Baht in Thailand, annually; "high" income was defined as earning >30,000 ringgit in Malaysia, $\geq$195,750 Baht in Thailand, annually. A fourth classification captured those refusing or unable to answer. We also control for cohort (the wave in which participants were first recruited into the ITC Project) and wave-pair, which accounts for secular changes in smoking behavior.

4.2.2.4. Smoking-Relevant Control Variables

Level of addiction was proxied by a measure of smoking intensity at baseline. Participants were asked, "On average, how many cigarettes do you smoke each day, including both factory-made and hand-rolled cigarettes?" Responses were measured continuously and were dummied as follows: $\leq$5 (referent), 6-14, 15+ cigarettes per day. Smoking frequency was assessed by the question, "Do you smoke every day or less than every day, including both factory-made and hand-rolled cigarettes?" Those

who responded “every day” were coded 1, indicating daily-smoking; participants who answered “less than every day” were coded 0.

Cigarette type was assessed by the question, “are you currently smoking factory-made or handrolled cigarettes.” Three dummy variables were created: factory-made (referent), both hand-rolled and factory-made, and hand-rolled. Noticed anti-smoking campaign was assessed by the question: “In the last 6 months, have you noticed any anti-smoking information or advertising from TV, radio, billboards, newspapers or magazines, on shop/store windows or inside shops/stores where you buy tobacco? Those who responded “yes” were coded 1, all others were coded 0.

Self-efficacy was assessed by the question, “If you decided to give up smoking completely in the next 6 months, how sure are you that you would succeed?” Responses comprised “not at all sure,” “somewhat sure,” “very sure,” and “extremely sure.” Participants who responded “very sure” or “extremely sure” were coded 1, indicating a high level of self-efficacy. Those who responded “not at all sure” or “somewhat sure” were coded 0.

We include a measure of “loosies” (loose or single cigarettes) as assessed by the survey item, “The last time you bought cigarettes for yourself, did you buy them by the carton, the pack, or as single cigarettes?” All participants who responded “as single cigarettes” were coded 1, all others were coded 0.

4.2.3. Statistical Analysis

4.2.3.1. Descriptive Analysis

Univariate statistics were used to describe the sample. Results are stratified by country (Malaysia and Thailand). We present frequencies as well as sample proportions displayed as column percentages.

4.2.3.2. Inferential Analysis

We used data from seven years (2006-2012) of the ITC-SEA. The data were arranged in three wave-pairs for Thailand and one wave-pair for Malaysia, in which we combined contiguous baseline and follow-up data.

Wave-pair 1	**Wave-pair 2**	**Wave-pair 3**	**Wave-pair 4**
Wave 1 + Wave 2	Wave 2 + Wave 3	Wave 3 + Wave 4	Wave 4 + Wave 5
TH: Jan 2005 – Sept 2006	TH: Aug 2006 – Mar 2008	TH: Jan 2008 – July 2009	TH: Apr 2009 – Apr 2011

MY: Jan 2005 – June 2007	MY: Aug 2006 – Sept 2008	MY: Feb 2008 – Nov 2009	MY: Jul 2009 – Apr 2012

The 2006-2012 period in Thailand, and 2009-2012 period in Malaysia, reflect a policy environment in which both countries had enacted graphic cigarette warning labels (i.e., existed in post-policy period).

Equations (1) to (3) depict the relationship between our smoking outcomes and salience of risk.

$$\text{Logit}\,(P(\text{SMOKING OUTCOMES}_{it})) = \beta_0 + \beta_1 \bullet \text{LABEL SALIENCE (any v. no)}_i + \beta_x \bullet X_{i(t-1)} \quad (1)$$

$$\text{Logit}\,(P(\text{SMOKING OUTCOMES}_{it})) = \beta_0 + \beta_1 \bullet \text{LABEL SALIENCE (high v. low)}_i + \beta_x \bullet X_{i(t-1)} \quad (2)$$

$$\text{Logit}\,(P(\text{SMOKING OUTCOMES}_{it})) = \beta_0 + \beta_1 \bullet \text{LABEL SALIENCE}_i + \beta_2 \bullet \text{LOOSIES}_i + \beta_3 \bullet (\text{LABEL SALIENCE} * \text{LOOSIES})_i + \beta_x \bullet X_{i(t-1)} \quad (3)$$

In equations (1) and (2), SMOKING OUTCOMES, which were measured at follow-up (time t), are expressed as a function of LABEL SALIENCE (the proxy for frequency of exposure to the graphic warning labels), and a vector of covariates (X), which were lagged to the baseline (t-1) of each data wave-pair. The difference between the models is in the measurement of LABEL SALIENCE. In equation (3), both LOOSIES and multiplicative interaction between LABEL SALIENCE and LOOSIES was added to the right-hand-side of the equation. In each model, β_0 is the regression constant.

We fitted equations (1) and (2) for each smoking outcome to test different thresholds of label salience. The measure of salience in equation (1) distinguishes any salience from no salience; that in equation (2) distinguishes high salience from low salience. The model associated with equation (3) explores differences in the effect of label salience on smoking outcomes according to whether participants consume loosies or packaged cigarettes. All models controlled for wave-pair (i.e., time), cohort, sex, age group, urban/rural status, education, income, level of addiction (proxied by daily smoking intensity), smoking frequency, type of cigarette smoked, self-efficacy, and noticed anti-smoking campaign. Analyses were run separately for the following sub-populations: 1) all adult smokers in Thailand, 2) male adult smokers in Thailand, and 3) all adult smokers in Thailand and Malaysia. Country differences were examined by including country-by-predictor interaction terms into the model. Since no by-country

interactions were found to be significant, the analyses reported here combined data from both countries. We also conducted analyses of the Thai sample, without the Malaysian sample, to assess Thai-specific outcomes. The limited size of the Malaysian sample hindered the ability to do the same with Malaysian data. To assess whether results would be significantly altered if we only included the male sample, we conducted ancillary analyses with female smokers removed from the data (there being insufficient women to do full interactive analyses).

We estimated the models with Generalized Estimating Equations (GEE) models, which generate population-averaged (marginal) effects of graphic cigarette warning labels on smoking outcomes. GEE is preferable to other techniques (e.g., fixed effects regression) for several major reasons. First, it corrects for intra-subject correlation that arises from repeated-measures data. Second, it estimates populationaveraged coefficients directly from observed data without restrictive assumptions about heterogeneity across individuals in the parameters [116]. Third, it accommodates dependent variables of various distributions (e.g., linear, logit, count, etc.) And finally, it permits the overt estimation of regression parameters on time-independent covariates, whose effects on the outcomes may be of interest to the investigator or policymaker.

Our analyses were conducted using SAS-Callable SUDAAN version 11.0.1 to account for the multistage sampling design and oversampling used in the ITC-SEA Project and the longitudinal nature of the data. Analyses were conducted using unweighted and weighted data for all models, with no significant differences observed between weighted and unweighted analyses. Results are presented for weighted analyses, with standard errors and model coefficients adjusted accordingly. As all outcomes are binary, we generate odds ratios and 95% confidence intervals. The QIC (Quasi-likelihood under the Independence model Criterion) statistic was used for comparing models fit with likelihood-based methods among otherwise equally suitable structures.

4.3. Results

Table 4.2 contains summary statistics for the country-stratified sample. Approximately 34.9% of the Malaysian sample and 39.15% of the Thai sample were high intensity smokers ($\geq$15 cigarettes per day) at baseline, with a mean of 13.18 and 11.14 cigarettes per day, respectively. At follow-up, 31.55% and 37.63% were high-intensity smokers, with a mean of 11.93 and 10.91 cigarettes per day in Malaysia

and Thailand, respectively. Aligning with national trends in each country, the number of male smokers in our sample far overweighed that of females with 98.71% and 94.87% of the sample being males in Malaysia and Thailand, respectively. The small number of female smokers limited our ability to stratify by gender, so we present results for a combination of males and females, controlling for sex (Table 4.3), as well as for males only (Table 4.4). With regard to our predictor variable, label salience, 5.29% of the Malaysian sample and 10.06% of Thai sample reported *never* reading the warning labels on cigarettes. Finally, purchasing loosies, which we examined as an effect modifier of smoking outcomes, was more common among Thai participants, with 22.04% purchasing their last cigarette in the form of a loose cigarette, as compared to 3.36% in Malaysia. Other relevant information may be obtained from Table 4.2.

4.3.1. Multivariable Model Summary

Tables 4.3 through 4.6 present results of regressions that estimated the association between smoking outcomes and exposure to graphic cigarette labeling (proxied by label salience); specifically, Table 4.3 presents results among all adult smokers in Thailand; Table 4.4 presents results among male adult smokers in Thailand; Table 4.5 presents results among adult male smokers in Thailand and Malaysia; and Table 4.6 presents results of our examination of loosies as an effect modifier among adult male smokers in Thailand and Malaysia. Once more, the outcomes were: high smoking intensity, reduced smoking intensity, plan to quit, quit attempts, cessation, and quit because of label. The regression models were estimated among relevant groups of participants. (For example, analysis of "high intensity smoking" is performed among current smokers only, whereas analysis of "quit because of label" is conducted exclusively among participants who were 'quit' at follow-up.) Two model specifications of each smoking behavior outcome were fitted to test for differences across measurement of label salience. Finally, in Table 4.6 we present results of regressions that estimated the association between smoking outcomes and exposure to graphic cigarette labeling after controlling for an interaction between label salience and loosies. All models controlled for wave-pair (i.e., time), cohort, sex, age group, urban/rural status, education, income, level of addiction (proxied by daily smoking intensity), smoking frequency, and type of cigarette smoked. Independent effects of adjustment variables are specified in relevant tables. Independent effects of control variables on smoking behaviors among *all adult smokers in Thailand* are

presented in Tables 4.7.a-f.; among *adult male* smokers in Tables 4.8.a-f.; and among *adult male smokers in Thailand and Malaysia* in Tables 4.9.a-f.

4.3.2. High Intensity Smoking

We found no significant association between high intensity smoking and label salience, except when examining loosies as an effect modifier. The odds of being a high intensity smoker (≥15 cigarettes per day) among male smokers in Thailand and Malaysia was *decreased* by approximately 63% among participants reporting any label salience and purchasing loosies, relative to those reporting *any* label salience and *not* purchasing loosies [OR=0.37, 95% CI (0.23, 0.60)]. Similarly, the odds of being a high intensity smoker among male smokers in Thailand and Malaysia was *decreased* by approximately 63% among participants reporting *high* label salience and purchasing loosies, relative to those reporting *high* label salience and *not* purchasing loosies [OR=0.37, 95% CI (0.20, 0.66)].

4.3.3. Reduced Smoking Intensity

The results of analyses that investigated the association between reduced smoking intensity and label salience were not significant among Thai smokers, nor among Southeast Asian smokers (Thai and Malaysian smokers combined).

4.3.4. Plan to Quit

The results of analyses that investigated the association between plan to quit and label salience were not significant among Thai smokers, nor among Southeast Asian smokers (Thai and Malaysian smokers combined).

4.3.5. Quit Attempt

With regard to making a quit attempt between baseline and follow-up waves, those who reported high label salience were significantly more likely to make a quit attempt than those reporting low salience among all smokers in Thailand [OR=1.28 (1.00, 1.64)], male smokers in Thailand [OR=1.29 (1.00, 1.66)], and male smokers in Southeast Asia [OR=1.25 (1.01, 1.55)].

4.3.6. Cessation

The results of analyses that investigated the association between cessation and label salience were not significant among Thai smokers, nor among Southeast Asian smokers (Thai and Malaysian smokers combined).

4.3.7. Quit because of label

Among baseline smokers who had quit at follow-up, the odds of attributing quit status to the graphic warning label was significantly higher among those reporting *any* label salience than those reporting *no* label salience among all quitters in Thailand [OR=1.62 (1.15, 2.29)] and male quitters in Thailand [OR=1.65 (1.17, 2.33)]. Additionally, the odds of attributing quit status to the graphic warning label was significantly higher among those reporting *high* label salience than those reporting *low* label salience among all quitters in Thailand [OR=1.36 (1.00, 1.86)] and male quitters in Thailand [OR=1.33 (1.01, 1.77)].

4.3.8. Moderating Effects of Loosies

Assessment of purchasing loosies as an effect modifier revealed that purchasing loosies did significantly moderate the association between: **high intensity smoking** and **attributing quit status to warning labels.** Specifically, purchasing loosies reduced odds of **high intensity smoking** among smokers in Thailand and Malaysia (versus those who did not purchase loosies) reporting *any label* salience [OR=0.37, 95% CI (0.23, 0.60)] and those reporting *high label* salience [OR= 0.37, 95% CI (0.20, 0.66)]. Purchasing loosies increased the odds of attributing quit status to warning labels among smokers in Thailand and Malaysia (versus those who did not purchase loosies) reporting *any label* salience [OR=1.42, 95% CI (1.02, 1.99)] and those reporting *high label* salience [OR= 1.51, 95% CI (1.02, 2.24)].

4.4. Discussion

This two-period longitudinal study examined the relationship between label salience and smoking behavior among adult smokers in Thailand and Malaysia. Prior research has already established the significant effect that graphic imagery has on label salience, and that label salience is predictive of quit attempts and cessation [15, 71, 94, 152]. However, previous research has focused on the changeover period from text-only to graphic warning labels, whereas this study examines salience of graphic warning labels solely in the *post*-policy implementation phase. The results of multivariable regression models

indicated that *any* salience was associated with increased odds of attributing **quit status to warning labels** among male smokers in Thailand and all adult smokers in Thailand (versus *no* salience). High salience was associated with increased odds of making a **quit attempt** among male smokers in Thailand, all smokers in Thailand, and male smokers in Thailand and Malaysia (versus *low* salience); and increased odds of attributing **quit status to warning labels** among male smokers in Thailand and all adult smokers in Thailand (versus *low* salience).

A secondary goal of our research was to assess the purchase of loosies as a potential effect modifier on label saliency due to its correlation with decreased exposure to the warning labels on cigarette packs. Some researchers have expressed concern that smokers may resort to covering cigarette packs or buying loosies as a defensive psychological mechanism [28, 30, 31] to avoid labels due to the fear evoked by graphic images [153]. As such, we hypothesized that purchasing loosies may reduce the impact of label saliency on smoking outcomes. However, our results indicate that purchasing loosies was actually associated with reduced odds of being a high-intensity smoker, as well as increased odds of attributing quit status to warning labels (among quitters). Previous studies have shown that some smokers purchase single cigarettes as a harm reduction strategy, and that using single cigarettes to reduce consumption is positively associated with quit intention [197]. However, the association between loosies*label salience and reduced smoking (between baseline and follow-up) was not significant, which indicates that smokers who purchase loosies may, generally, be lower intensity smokers than those who do not purchase loosies. Though we do not condone the sale of loose cigarettes, our results provide heartening evidence that the availability of single cigarettes, does not negate the effect of graphic cigarette warning labels as a tobacco control measure. Furthermore, the fact that quitters with high label salience who purchased loosies were more likely to attribute their quit status to warning labels (versus those who did not purchase loosies) further allays concerns that label salience is reduced by the purchase of loose cigarettes.

Our findings also suggest that our two variant measures of label salience (any v. no salience and high v. low salience) have seemingly comparable effects on smoking behavior, with the exception of quit attempts. *High* salience was significantly associated with increased odds of making a quit attempt between baseline and follow-up, as compared to *low* salience. The same association was not found when comparing *any* salience versus *no* salience. This indicates that the frequency with which people read

labels does appear to have an effect on certain smoking outcomes. It is plausible that 'ever' reading graphic warning labels is enough to affect behavioral change among a specific sub-population, perhaps people for whom graphic imagery evokes a more emotional response. Examples of such include those with firsthand experience with health effects of smoking, those receiving pressure from a child or a spouse, or those with a loved one who suffered or passed away from smoking-related disease. Further research is needed to better understand the factors that predict quit attempts and successful cessation among different sub-populations.

Furthermore, the influence of several demographic and social factors is revealed by our analyses—albeit as direct effects, rather than as mediators. With regard to ***country of residence***, living in Thailand as compared to Malaysia was associated with reduced odds of *reduced smoking intensity* among adult male smokers in model 1 [OR=0.33, 95% CI (0.14, 0.80] and model 2 [OR = 0.33, 95% CI (0.13, 0.80)]; decreased odds of *planning to quit* within 6 months among adult male smokers in model 1 [OR=0.47, 95% CI (0.33, 0.66)] and model 2 [OR=0.46, 95% CI (0.32, 0.65)]; increased odds of making a *quit attempt* in model 1 [OR=1.41, 95% CI (0.42, 1.95)], decreased odds of *cessation* in model 1 [OR=0.62, 95% CI (0.42, 0.92)] and model 2 [OR=0.63, 95% CI (0.42, 0.94)], and increased odds of attributing *quit status* to warning labels in model 1 [OR=3.35, 95% CI (2.32, 4.81)] and model 2 [OR=3.29, 95% CI (2.29, 4.72)]. With the exception of quit attempt, these country differences reveal that the graphic labels were more effective in Malaysia than in Thailand with regard to behavioral change. It is possible that the long history of anti-tobacco campaigns and policies in Thailand primed participants to the warning labels, while the novelty of the messages in Malaysia may have increased their impact and effectiveness [13, 151]. Interestingly, adults in Thailand were more likely to attribute their quit status to the warning labels than adults in Malaysia. It is possible that the labels effected behavioral change through mechanisms relating to social climate or social stigma surrounding tobacco use without smokers attributing the change to warning labels directly. 'Social denormalization,' a process that seeks 'to push tobacco out of the charmed circle of normal desirable practice to being an abnormal practice' [118], is widely regarded as essential to successful policy outcomes.

Other factors found to have a significant effect on smoking outcomes include: cohort, wave-pair, (time) sex, age, urban/rural status, education, income, smoking frequency, level of addiction (proxied by daily smoking intensity), type of cigarette smoked, noticed anti-smoking campaign, and self-efficacy.

Cohort was associated with: *reduced smoking intensity* among all adult smokers in Thailand and male smokers in Southeast Asia; *plan to quit* among male smokers in Thailand and male smokers in Southeast Asia; *quit attempts* among males in Southeast Asia, and *quit because of label* among males in Thailand. **Wave-pair (time)** was associated with *quit attempt* among all adult smokers in Thailand and male smokers in Southeast Asia; and *quit because of* label among all adults in Thailand and males in Southeast Asia.

Sex was associated with *high intensity smoking* among adult smokers in Thailand; *plan to quit* among adult smokers in Thailand, and *quit because of label* among adult smokers in Southeast Asia. **Age** was associated with *high intensity smoking* among all smokers in Thailand, male smokers in Thailand, and male smokers in Southeast Asia; *reduced smoking intensity* among all adult smokers in Thailand and adult smokers in Southeast Asia; *quit attempt* among male smokers in Southeast Asia*; cessation* among males in Southeast Asia*;* and *quit because of label* among all smokers in Thailand and male smokers in Thailand. **Urban/rural status** was associated with *quit attempt* among male smokers in Southeast Asia. **Education** was associated with *reduced smoking intensity* among male smokers in Thailand. **Income** was associated with *high intensity smoking* among all smokers in Thailand, male smokers in Thailand, and male smokers in Southeast Asia; *plan to quit* among all smokers in Thailand and male smokers in Thailand; and *quit attempts* among male smokers in Thailand and male smokers in Southeast Asia.

Smoking frequency (daily v. non-daily smoking) was associated with *high intensity smoking* among all adult smokers in Thailand, male smokers in Thailand, and male smokers in Southeast Asia; *reduced smoking intensity* among all adult smokers in Thailand, male smokers in Thailand, and male smokers in Southeast Asia; *plan to quit* among all adult smokers in Thailand, male smokers in Thailand, and male smokers in Southeast Asia; *quit attempt* among all adult smokers in Thailand male smokers in Thailand, and male smokers in Southeast Asia; *cessation* among all adult smokers in Thailand and male smokers in Thailand; and *quit because of labels* among all adult smokers in Thailand, male smokers in Thailand, and male smokers in Southeast Asia. **Level of addiction**, proxied by daily smoking intensity,

was significantly associated with *plan to quit* among male smokers in Southeast Asia; *quit attempt* among all adult smokers in Thailand and male smokers in Southeast Asia; *cessation* among all adult smokers in Thailand and male smokers in Southeast Asia; and *quit because of labels* among all adult smokers in Thailand, male smokers in Thailand, and male smokers in Southeast Asia. **Type of cigarette smoked** (FM, RYO, or FM + RYO) was significantly associated with *high intensity smoking* among males in Southeast Asia; *reduced smoking intensity* among all adult smokers in Thailand, male smokers in Thailand, and male smokers in Southeast Asia; *cessation* among all adult smokers in Thailand and male smokers in Thailand; and *quit because of label* among all adult smokers in Thailand, male smokers in Thailand, and male smokers in Southeast Asia. **Noticed anti-smoking campaigns** was associated with *plan to quit* among male smokers in Thailand. Finally, **self-efficacy** was associated with *high intensity smoking* among all adult smokers in Thailand, male smokers in Thailand, and male smokers in Southeast Asia; *plan to quit* among all adult smokers in Thailand, male smokers in Thailand, and male smokers in Southeast; *cessation* among all adult smokers in Thailand, male smokers in Thailand, and male smokers in Southeast Asia; and *quit because of labels* among all adult smokers in Thailand, male smokers in Thailand, and male smokers in Southeast Asia.

This investigation builds on existing research in several notable ways. First, the use of seven years of data allows us to circumvent the undue influence of extraneous policy events and generate sufficient person-wave observations to control for several relevant sociodemographic and smokingspecific variables. Second, to our knowledge, this is the first study to examine the post-implementation adult response to graphic warning labels in Malaysia. Third, our examination of the effect of warning labels on behavioral *outcomes* builds upon previous studies of behavioral *intention.* Lastly, our investigation of the moderating effects of loosies is novel, and extremely relevant, given the popularity of loose cigarettes (over 20% of our Thai sample reported buying loose cigarettes at baseline) and concerns over the effect of loosies as an avoidance tactic. We should note, however, that although we did control for income, this investigation did not directly assess the potential economic influences driving the purchase of loosies, which may be an important predictor of lower smoking intensity.

There are, nevertheless, limitations that should be noted. First, the relatively small size of our Malaysian sample hindered our ability to conduct Malaysia-specific analyses. Instead, after ensuring there were no significant country-by-predictor interaction terms, we combined data from both countries. Similarly, the small number of female smokers in our sample, while representative of smoking trends in Southeast Asia, prevented us from stratifying analyses by gender.

Additionally, we cannot be certain that extraneous tobacco control efforts and policies did not affect our smoking outcomes. In an effort to partially control for other sources of anti-tobacco information, we included a measure of noticing anti-smoking campaigns through multiple modalities (television, radio, billboard, etc.), which may have resolved some of these external influences. Furthermore, we do not account for changes to the graphic warning label policy in Thailand, including the introduction of a new set of graphic warning labels in February 2007, between waves 2 and 3, which likely impacted label salience. Previous research has shown that novelty effects impact overall salience, as well as stimulate cognitive and behavioral reactions [14, 71, 120]. Additionally, our measure of loosies was assessed by asking participants about the source of the *last cigarette* they smoked. It is unclear how frequently they purchase loose cigarettes, or if loosies are their usual form of purchase. Lastly, though our population was replenished at every wave, we do not account for dropout in our analyses. A weighted generalized estimating equation (GEE) approach may be more appropriate for datasets prone to missing observations, as they extend the traditional GEE approach to better account for dropout [183], assuming that data are missing at random.

In summary, graphic cigarette warning label salience is associated with increased odds of reduced smoking intensity, as well as increased odds of making a quit attempt. It is likely that reading warning labels has more immediate effects on certain sub-populations for whom the labels trigger a more pronounced emotional response. Future research is needed to better understand additional factors that mediate the effect of label salience on quitting behavior. Our results support the notion that reading warning labels more frequently positively impacts smoking outcomes; as such, efforts should be made to increase salience through the introduction of new graphics and messages, as novelty effects have been shown to increase warning label salience [13, 151]. With over 50% of the world's smokers living in Asia [79], it is imperative that we promote anti-tobacco efforts in this region and make global tobacco control a

priority. Understanding the mechanisms through which graphic warning labels effect, and sustain, behavioral change is critical to enhancing their impact on population health.

Chapter 5. Discussion

5.1. Overview of the dissertation

This longitudinal study of smoking outcomes in Malaysia and Thailand aimed to expand the limited knowledge of smoking intention, susceptibility, cognitive processing, and behaviors among youth and adults after the implementation of graphic cigarette warning labels.

First, to assess the effect of the graphic warning label policy on youth smoking outcomes, we used 'country of residence' as a proxy for the implementation of the policy. We limited our data to the timeframe capturing the pre-implementation period in Malaysia and post-implementation period in Thailand. As such, Thailand represented the experimental group and Malaysia served as a control in our quasi-experimental design. Our primary outcomes of interest were: smoking intention (plan initiate smoking among non- and never-smokers, and plan to continue smoking among smokers), smoking susceptibility (among non- and never-smokers), label saliency, and cognition of risk. Our secondary outcomes were behavioral, and were measured by 5 separate variables: smoking initiation, high-intensity smoking, quit attempt, increased smoking intensity, and reduced smoking intensity. Results for smoking behavior were preliminary, as the size of the sample of youth smokers was too small to achieve statistical significance. We fitted separate, gender-stratified, models of the effect of graphic cigarette labeling for each smoking outcome. A set of additional control variables account for cultural/attitudinal, social/normative, and intrapersonal factors. Such factors, derived from the Theory of Triadic Influence (TTI) [57, 58], have been shown to predict adolescent smoking behavior in previous research on youth smoking and other substance abuse [59-63].

The study then examined the effect of *frequency* of exposure to graphic cigarette warning labels on the same set of smoking outcomes (smoking intention, susceptibility, and behaviors) among youth in Thailand and Malaysia. Cognition of risk was used as a proxy for frequency of exposure, due to the collinearity between exposure and smoking behavior. Though the small size of our Malaysian sample precluded analysis solely among Malaysian youth, we combined data from Thailand and Malaysia and examined differences in outcomes across countries.

Finally, we examined the effect of frequency of exposure to graphic cigarette warning labels on smoking behaviors among adult smokers in Malaysia and Thailand. Specific outcomes included: high smoking intensity ($\geq$15 cigarettes per day), reduced smoking intensity at follow-up, plan to quit within 6 months, quit attempt between baseline and follow-up, cessation between baseline and follow-up, and

attribute quit status to warning labels (among quitters). To circumvent the perverse effect that arose from the conflation of the dependent (smoking behavior) and independent (exposure) variables, we utilized label saliency as a proxy for frequency of exposure. A secondary goal of our analysis was to examine the moderating effects of purchasing loose cigarettes on the association between label salience and smoking behaviors.

The three aims of the study fit within the conceptual framework of the effectiveness of graphic cigarette warning labels, diagramed in figure 1.1 examining how policy implementation and exposure to the labels affect smoking intentions, susceptibility, and behaviors. The framework outlines the overarching theoretical constructs through which exposure to the labels leads to smoking outcomes, but this study examines specific aspects of the framework, and identifies individual, social, cultural, and smoking-related psychosocial characteristics that affect smoking outcomes. In the following section, the main findings and interpretations are summarized.

5.2. Summary of the findings

5.2.1. Chapter 2

Table 5.1 contains a summary of findings from Chapter 2. Analyses of the effect of the graphic cigarette label policy implementation in Thailand, using Malaysia as a control, revealed significant effects on youth smoking intention, susceptibility, label salience, and cognition of risk.

Among male smokers, living in Thailand (which proxies the graphic cigarette labeling policy) significantly reduced the odds of planning to continue smoking by roughly 50%. Among non- and never-smokers females, living in Thailand reduced odds of planning to smoke by between 65% and 75% compared with living in Malaysia. Country of residence was also significantly associated with odds to plan to quit within 6 months among male smokers. Male youth smokers in Thailand were 2.7 to nearly 3 times more likely to quit smoking than youth smokers in Malaysia. Among female non- and never-smokers, residing in Thailand was associated with significantly lower odds of smoking susceptibility. Among male non-smokers and never-smokers, label salience was also significantly associated with country of residence. The odds of reporting high (vs. low) label salience among male non-smokers was elevated by approximately 50% in Thailand, relative to Malaysia. Similar, but stronger, results were found for male never-smokers, where label salience was elevated by approximately 90-104% among Thai youth, as

compared to their Malaysian counterparts. The results were similar for female non-smokers and neversmokers. Thai female non- and never-smokers had approximately double the odds of high label salience of similar Malaysian females. Among female non- and never-smokers, participants living in Thailand had significantly higher odds of high cognition of risk (vs. low) than in Malaysia. With regard to behavior, in none of the models did graphic cigarette labeling achieve statistical significance. Nevertheless, all coefficients were in the expected direction, and one outcome (quit attempt within the past year) had a strong trend toward statistical significance. Analysis of the independent effects of covariates revealed that peer smoking, smoking at home, and societal influence were significantly associated with smoking outcomes among youth.

Our youth findings align with those of some earlier research on the *adult* response in Southeast Asia, although differences in study frame, design, stratification, and models of smoking preclude direct comparison [22, 71, 105]. Findings from this research support the implementation of graphic cigarette warning labels in Southeast Asia, as they have positive effects on strong predictors of youth smoking behavior, namely, smoking intention, susceptibility, label saliency, and cognition of risk.

5.2.2. Chapter 3

Table 5.2 contains a summary of findings from Chapter 3. We sought to build upon our analyses in Chapter 2 by examining the association between frequency of exposure to graphic cigarette warning labels and smoking outcomes. The distinction between measuring the impact of the graphic labeling *policy* versus the impact of *frequency of exposure* to the label is subtle but extremely important. The analyses conducted in Chapter 3 allow us to further explore another mechanism through which labels are effective: perhaps the implementation of a tobacco control policy effectively increases the anti-smoking climate and culture in a society, or perhaps the labels work through direct exposure to, and communication of, visual communication of risk, or both. While we do not test the pathways directly, Chapter 3 allows us to examine the effectiveness of labels through a direct measure of cognition of risk.

Our findings indicate that, among Thai *male non-smokers,* the odds of susceptibility to smoking were approximately 27-28% lower among participants with high cognition of risk (“a lot”) than those with low cognition of risk (“a little” or “not at all”). With regard to smoking behavior, our results indicate that the odds of smoking initiation were 62-63% lower among participants with high cognition of risk than those

with low cognition of risk. Among Malaysian male youth smokers, the odds of smoking initiation were reduced by 40% among participants with high cognition of risk than those with low cognition of risk. The odds of reducing smoking between baseline and follow-up waves were significantly higher among participants with high cognition or risk than those with low cognition of risk. Surprisingly, we found that both the odds of being a high intensity smoker (>10 cigs) and the odds of increasing smoking intensity between baseline and follow-up were associated with high cognition of risk. However, we hypothesize that the observed association between risk cognition and high intensity smoking and increased intensity may be due, in part, to reverse causality, as heavy smokers are more likely to have experienced smokingrelated side effects, and are therefore more likely to have a higher cognition of the risks associated with smoking than non-smokers or lower intensity smokers. Taken together, results indicate that harm-related thoughts stimulated by labels (cognition of risk) is significantly associated with decreased odds of susceptibility to smoking, decreased odds of smoking initiation, and increased odds of a reduction in smoking intensity among male youth.

Additionally, our analyses revealed other covariates that were significantly associated with smoking outcomes, specifically: wave-pair (time), country of residence, peer smoking, and being of legal smoking age. Of particular interest was country of residence, as this is the first study to utilize postimplementation data from Malaysia, and differential effects by country have not been studied. Living in Thailand as compared to Malaysia was associated with increased odds of planning to smoke among male youth non-smokers, as well as an 89% increase in smoking susceptibility among male youth nonsmokers. These country differences reveal that the graphic labels may have been more effective in Malaysia than in Thailand, with increased odds of planning to smoke and susceptibility to smoking reported among Thai youth than Malaysian youth. It is possible that the long history of anti-tobacco campaigns and policies in Thailand primed youth to the warning labels, while the novelty of the messages in Malaysia may have increased their impact and effectiveness among youth [13, 151].

5.2.3. Chapter 4

Tables 5.3.a-b contain a summary of findings from Chapter 4. Similar to Chapter 3, Chapter 4 examines the impact of frequency of exposure to graphic cigarette warning labels; however, outcomes are studied among the adult smoker population and are limited to smoking behavioral outcomes. Furthermore,

as predictors of adult smoking are different than those of youth smoking, our models of smoking are varied. In our adult models, we control for demographic variables comprised of age, urban/rural status, education, and income. We also control for smoking-related variables, specifically: smoking frequency (daily v. nondaily), level of addiction (proxied by daily smoking intensity), type of cigarette smoked (factory made v. roll your own), noticing anti-smoking campaigns, and self-efficacy. To assess the effect of the graphic warning label policy on smoking behavior, we utilized a measure of label salience, known in this literature as "reading" labels. We examined two variant measures of label salience: *any* versus *no* salience, and *high* versus *low* salience. A secondary aim of this chapter was to examine the moderating effects of purchasing loose cigarettes on the association between label salience and smoking outcomes.

We found no significant association between high intensity smoking and label salience, except when examining loosies as an effect modifier. The odds of being a high intensity smoker ($\geq$15 cigarettes per day) among male smokers in Thailand and Malaysia was *decreased* by approximately 66% among participants reporting any label salience and purchasing loosies, relative to those reporting *any* label salience and *not* purchasing loosies. Similarly, the odds of being a high intensity smoker among male smokers in Thailand and Malaysia was *decreased* by approximately 67% among participants reporting *high* label salience and purchasing loosies, relative to those reporting *high* label salience and *not* purchasing loosies.

With regard to making a quit attempt between baseline and follow-up waves, those who reported *high* label salience were significantly more likely to make a quit attempt than those reporting *low* salience among all smokers in Thailand, male smokers in Thailand, and male smokers in Southeast Asia. Among participants who were quit at follow-up, the odds of attributing quit status to the graphic warning label was significantly higher among those reporting *any* label salience than those reporting *no* label salience among all quitters in Thailand, and male quitters in Thailand. Additionally, the odds of attributing quit status to the graphic warning label was significantly higher among those reporting *high* label salience than those reporting *low* label salience among all quitters in Thailand, and male quitters in Thailand.

Our findings indicate that our two variant measures of label salience (any v. no salience and high v. low salience) have seemingly comparable effects on smoking behavior, with the exception of quit

attempts. *High* salience was significantly associated with increased odds of making a quit attempt between baseline and follow-up, as compared to *low* salience, whereas we did not observe the same association when comparing *any* salience versus *no* salience. This indicates that the frequency with which people read labels does appear to have an effect on certain smoking outcomes.

All of our demographic and social factors were found to significantly affect adult smoking outcomes, albeit different outcomes among different sub-populations (smokers v. quitters, all adults v. males-only, Thais and Malaysians v. Thais-only). Of particular importance is the country of residence variable. We found that living in Thailand as compared to Malaysia was associated with reduced odds of *reduced smoking intensity* among adult male smokers; decreased odds of *planning to quit* within 6 months among adult male smokers; increased odds of making a *quit attempt*; decreased odds of *cessation*; and increased odds of attributing *quit status* to warning labels. With the exception of quit attempt, these country differences reveal that the graphic labels were more effective in Malaysia than in Thailand with regard to behavioral change. We hypothesize that this observed effect may be due to the priming effect of Thailand's longstanding history of anti-tobacco campaigns and policies. It is also interesting to note that adults in Thailand were more likely to attribute their quit status to the warning labels than adults in Malaysia. We hypothesize that warning labels may have indirectly affected Malaysians through social denormalization and a cultural shift around tobacco. This aligns with previous research that found that societal norms and individuals' perceptions of the social undesirability of smoking are significantly associated with smoking behavior in both Malaysia and Thailand [198]. As the graphic labeling policy was the first national tobacco control policy in Malaysia, it is possible the effect on social denormalization was more pronounced among Malaysians than Thais.

5.3. Limitations

There are several potential threats to the validity of our research findings. The two main threats are history and underreporting of smoking, particularly among youth. With regard to history, policies and anti-smoking campaigns were implemented over the course of the study timeframe which may contaminate findings. These peripheral anti-tobacco campaigns were controlled for as best as possible, by including a measure of "noticed anti-smoking campaigns" in our adult analyses. We did not control for

anti-smoking campaigns in our youth analyses, as we were limited by a smaller sample size which hindered model convergence.

Examples of other policy measures employed during the course of our study period include: increased taxation, bans on tobacco advertising, ban on price promotions for tobacco products, smoking bans, and bans on use of misleading terms and descriptors. Taxation is a particular important factor, as youth are especially sensitive to price changes in cigarettes [199], as are certain sub-populations of adults, specifically younger adults and those with lower income [200].

The self-reported measure of smoking behavior may also be viewed as a limitation of this research; although behaviors were not validated by biochemical tests, studies have indicated that selfreported smoking status is validated by measured serum cotinine levels, which yield similar prevalence estimates. Underreporting of smoking behavior is more common among younger adolescents and cases where the social desirability is strongest. The ITC team tried to minimize social desirability bias by having youth complete paper and pencil surveys in a private area of the home and by stressing the confidentiality of the findings. Nevertheless, the actual prevalence rates of youth smoking may be somewhat higher than indicated by the data as some underreporting is likely greater for surveys conducted in the home. There has been some evidence that underreporting of smoking in Malaysia may be particularly high in school surveys given that smoking is a disciplinary offence for school students in Malaysia.

Another potential limitation of this study is that the policy of interest was not implemented at one specific time; the policy was rolled out across provinces/states in Thailand and Malaysia over the course of a year. Further, we do not measure exposure to the graphic warning labels directly, instead, we use proxies such as country (chapter 2), cognition of risk (chapter 3), and label salience (chapter 4). The use of effective proxies was imperative given the correlation between exposure to warning labels and smoking behavior. Preliminary analyses (not presented) demonstrated this perverse effect and indicated those who were exposed to labels more frequently smoked more, and those who reported smoking more were exposed to the label. This reverse-causality could not be disentangled, as such, effective proxies for exposure were utilized.

Additionally, the relatively small size of our Malaysian sample hindered our ability to conduct Malaysia-specific analyses. Instead, after ensuring there were no significant country-by-predictor

interaction terms, we combined data from both countries. Similarly, the small number of female smokers in our sample, while representative of smoking trends in Southeast Asia, prevented us from examining behavioral outcomes among females only.

Furthermore, the mode of data collection is slightly varied across countries: in Thailand, data were collected via face-to-face survey for adults; in Malaysia, data were collected via face-to-face survey, as well as via telephone survey. Both countries obtain youth data via self-administered mail survey. Additionally, for reasons of administration and cost, the number of primary sampling units within strata was relatively small, and the sample of households within the primary sampling units was geographically clustered. Such a sample cannot be as representative of the national population as a simple random sample of the same number of households.

Furthermore, as this is a longitudinal survey, drop-out among participants is not uncommon. We do not account for drop-out in our analyses, and suggest that future research accounts for this with statistical methodologies such as Weighted Generalized Estimating Equations (GEE) [183]. Weighted GEE may reduce bias introduced by missing observations caused by dropouts or skipped interviews, assuming data are missing at random.

Lastly, though there were many models fit and hypotheses tested, we did not adjust for multiple testing, hence we cannot be certain that certain positive results are not due to Type I error (i.e., chance). However, we tried to support out positive results with meaningful explanations. This study was exploratory in nature, even as we tried to drive the models by theoretical and topic-oriented considerations.

5.4. Policy recommendations and future research directions

Tobacco control has a long history of employing theory and evidence in developing interventions. The need for this culture of evidence-based practice is driven, in part, by the need to make compelling cases to government officials and policy-makers in the face of opposition from a powerful tobacco industry, and the need for persuasive communications to the community asking them to change a behavior which is well entrenched, and involves consuming an addictive substance.

Our results are consistent with prior research demonstrating the effectiveness of graphic cigarette warning labels to increase salience and stimulation of cognition reactions that ultimately lead to changes in behavioral intention and behavioral outcomes. The study provides strong support for the introduction of graphic warning labels in other developing countries where benefits may be even greater given the lower literacy rates and generally lower levels of readily available health information on the risks of smoking.

Future research should further investigate the impact of graphic warning labels on smoking outcomes, particularly among females (both among youth and adults). The female market represents an opportunity for tobacco companies, as prevalence among this sub-population remains low. Our sample of female smokers was extremely limited, thus hindering our ability to conduct female-specific analyses. Furthermore, our sample of adolescent and young teenage smokers (under the age of 15) was also limited, limiting our ability to conduct analysis of age-effects among youth.

The need for tobacco control strategies in other Southeast Asian countries is paramount. Indonesians represent a particularly vulnerable population that is being targeted heavily by tobacco companies. While smoking rates are declining in many western countries, the opposite is happening in the Republic of Indonesia, where over 60% of the male population regularly smokes and uses tobacco. Smoking has become ingrained in Indonesian culture where some children are having their first cigarette by the age of four. Indonesia's economy is dependent upon the tobacco industry, which has proven to be extremely profitable. Furthermore, many Indonesians make their livelihood through tobacco farming, and are surrounded by cigarettes from an early age [201]. Smoking regulations in Indonesia are few and far between, making residents an easy target for smoking uptake. Indonesia represents a developing country in Southeast Asia that stands to benefit immensely from increased tobacco control policies, such as the implementation of graphic cigarette warning labels.

Given their great reach, warning labels on cigarette packs may be one of the few tobacco control policies that have the potential to reduce communication inequalities across populations. As the attention of the tobacco companies has shifted to developing countries, the effectiveness of graphic warning labels among Southeast Asians suggests an opening for effective strategies to communicate risk, prevent initiation, reduce intensity, and promote cessation. Furthermore, Mahood (1999) argues that an effective

warning system will create a situation of informed consent regarding the nature of the risks, the magnitude of the dangers and the probability of occurrence among smokers regarding the risks of tobacco smoke [38, 202]. As a communication device, on-pack messages should follow the principles of communication theory and practice. Policies that establish strong graphic warning labels on tobacco packaging may be instrumental in reducing the toll of the tobacco epidemic, particularly within vulnerable populations [10].

Socioeconomic indicators as predictors of all cause mortality in the United States

Hunter College School of Public Health

2180 Third Ave

New York, NY 10035

ABSTRACT

The theoretical social construct of socioeconomic status (SES) if often difficult to quantify. Attempts to define this construct result in commonly used indicators based on education, income, occupation and accumulated wealth. Despite this, there is no consistent collection of socioeconomic status indicators across population surveys. The aim of this study is to investigate related SES predictors from the National Health Interview Survey (NHIS) as drivers for all cause mortality. Leveraging linkage to the National Death Index (NDI) data, the time-to-event indicator was calculated for nearly all participants (94%). Principal Components Analysis (PCA) for categorical variables was used to identify a set of risk scores most associated with all cause mortality.A survey Cox proportional hazards regression was then used to create a composite risk score that was found to be predictive of all cause mortality. A Kaplan-Meier plot shows the predictive ability of the tertiles of the composite risk score. All composite scores were significantly influential influential to survival. The dental visits, insurance and education component had the greatest protective effect of the event compared to the other composite scores. This approach can be used to combine several SES indicators into one composite risk score.

INTRODUCTION

The theoretical constructs related to social status are based on a variety of indicators such as education, occupation, household income and accumulated wealth. These indicators are extensively studied under the umbrella term of socioeconomic status (SES). The effects of SES on health outcomes and in disparities research have been widely investigated alongside race/ethnicity.[1,2] However, due to the dynamic nature of SES, difficulty of collection, and lack of precision and reliability,[3] there is no agreement on a particular set of indicators for socioeconomic status in population surveys. Surveys like the Demographic and Health Survey have data-specific indices for measuring SES although this measure does not translate well into multiple countries with varying levels of wealth.[4] At least in the United States, there is no comprehensive set of indicators for SES that are routinely collected in population-wide surveys.[1,5] In 1997, Krieger and colleagues found that only two-thirds of the states included education level information of mothers in birth certificates and one-fourth of states published that of fathers.[6] The authors found no data was collected concerning income level for any of the national registries or certificates investigated at the time.[6] The latest Health, United States 2013 report prepared by the CDC contains important socioeconomic indicators like education, household poverty level and insurance status on the majority of tables presented.[7] Krieger and colleagues detailed the need for carefully considered measures of socioeconomic position that would account for concerns of privacy and confidentiality.[6]

Typically, research results report on the relationship between SES and an outcome of interest with little to no explanation on the mechanism of the effect.[3] Shavers makes a distinction between two types of SES measures: 1) compositional measures 2) contextual measures.[3] Compositional measures of SES focus on indicators that directly relate to the individual such as

occupation, education, and income and wealth. Contextual measures of SES are related to the individual's environment and can include measures of neighborhood, county, as well as census tract levels of SES.[3]

Shavers contends that contextual measures of SES often do not correlate well with individual measures of SES.[3] This is likely due to the generalization or aggregation of region characteristics in terms of SES levels. Contextual measures of SES are sometimes the only option for approximating SES at the aggregate level when such data is not available at the individual one.[8] Therefore, census data is often used to obtain an average measure of socioeconomic status at the tract level.[5]

It is important to note that individual measures of SES are not without flaws. Problems can arise when measures of SES in particular groups of people (e.g. retirees) do not reliably reflect the true SES, especially in measures of occupation.[1] Individual measures of education fail to capture on the job training opportunities, other personal capital investments made,[1] and shifts in the distribution of education. Household measures of income may not reflect accurate levels of SES if there is unequal access to household wealth.[1] Despite this, Duncan and colleagues support the use of household income as an optimal measure of SES for being more sensitive to changes in the SES and health relationship. Particularly, disposable income is a good indicator of standard of living and the life opportunities experienced.[1] Age, race-ethnicity and sex are known to vary in the distribution of SES indicators.[1] The literature on SES and mortality in the NHIS has shown the education gradient of risk among preventable and less preventable diseases.[9]

The literature tends to focus on individual compositional measures of SES, such as income, occupation, and education [1–3,9]. The present study aims to compare and combine groups of related individual SES indicators from the National Health Interview Survey (NHIS) in order

to create a single risk score for all cause mortality. These groups of SES indicators can be considered social drivers for all cause mortality within the scope of the NHIS and the linked National Death Index (NDI) dataset. In contrast to singular measures of SES, combinations of SES predictors can be more advantageous in predicting mortality. In turn, these sets of SES predictors can be further investigated in order to target and focus on modifiable risk factors.

METHODS

Data

The National Health Interview Survey (NHIS) is an ongoing cross-sectional survey conducted by the National Center for Health Statistics a division of the Center for Disease Control and Prevention (CDC). The NHIS monitors national health trends by asking participants about a wide range of health topics.[10] It is a nationally representative sample of noninstitutionalized adults, 17 years of age or over, residing in the United States via personal household interviews. The NHIS survey data was recently linked to mortality data from the National Death Index (NDI).[11] The mortality data linkage was done based on probabilistic matching of NDI records with NHIS survey data by the CDC up until the year 2011.[11] The publicly available data were be obtained from the CDC website (www.cdc.gov/nchs) and included survey years from 1998 to 2003 due to similar complex survey sampling strategies. In order to combine across years, survey weights were averaged by the number of years in the entire data thus, all weight estimates were divided by 6 for each year included in the data. All analyses were done using R statistical software (version 3.1.2).[12] The "survey" package written by Thomas Lumley and was used for adjusting for complex survey sampling. The "SAScii" and "readr" packages written by Anthony D'Amico and Hadley Wickham, respectively, were used to read and parse fixed width and SAS files downloaded from the CDC FTP website.

Data analysis plan

Widely used methods for dimension reduction are based on the principal component analysis (PCA) or factor analysis.[13] Separate PCA analyses were run each for (1) imputed income and poverty ratios and (2) for categorical variables related to health care access, utilization, insurance status and education. Imputed income variables included household income and poverty ratio, which were provided in the data. These variables were obtained from multiple imputation procedures (5 in total) by survey year. Pearson correlations were used to calculate the correlation matrix for the income and poverty ratio component. Kolenikov and colleagues highlight the consequences of using of discrete variables in PCA without the appropriate methodology.[14] Hence, polychoric correlations were used to create a correlation matrix to derive the principal components for these discrete categorical variables. Insurance status was a recoded variable derived from a combination of coverage status and private insurance coverage.

The time-to-event indicator was calculated from the linked mortality dataset simply by obtaining the difference between the year of death and the year the survey was administered. Participants without a valid year of death are assumed to be alive up until 2011, the last date of collection of mortality data, and were right censored. Mortality data was then merged to survey and income data by participant-level identification numbers.

The survival function was plotted using nonparametric Kaplan-Meier curves. Finally, a Cox Proportional Hazards model for survey data was used to build a model that included the extracted components from the PCA analyses controlling for age and gender.

Measures

Principal Components

Items under the first component describe the ability to afford health care services like

prescription medicines, mental health care, and dental care by asking, “During the past 12 months, was there any time when you needed any of the following but didn’t get it because you couldn’t afford it?” These items load highly and are part of the first component named “Affordability of Care.” The second component describes variables that are related to use and frequency of primary health care. Questionnaire items that load highly in this component ask, “Is there a place that you usually go to when you are sick or need advice about your health?” and “About how long has it been since you last saw or talked to a doctor or other health care professional about your own health?” The last component included dental health care use, insurance type and educational attainment. High loading questionnaire items in this component asked, “About how long has it been since you last saw or talked to a dentist? Include all types of dentists, such as orthodontists, oral surgeons, and all other dental specialists, as well as dental hygienists” and “What is the highest level of school you have completed or the highest degree you have received?” Detailed descriptions of the items included in the principal components are provided in Appendix I.

RESULTS

Merging with National Death Index records resulted in a loss of 6% of participants; thus, a total of 179,012 participants were included in the analyses. The mortality event occurred in 11.5 % of the survey sample with a standard error of 0.001. The survey adjusted mean age of the sample was 45 years with a standard error of 0.10. Fifty-two percent of the survey sample were female.

Table 1 shows the results of the principal components analysis based on select questions from the adult sample related to socioeconomic status. Variables with component loadings greater than 0.8 are shaded dark gray. Participants able to afford health care services and

prescription medicines score highly in the first component of affordability of care. Participants with a usual primary care location and who have recently seen their primary care provider score highly in the primary care use and frequency component. Participants with high education, private insurance status and recent dental visits score highly in the dental, insurance, and education component.

Table 2 shows the results of the survey Cox proportional hazards regression model that includes all components and covariates (including income, age, and gender). Affordability of care, income, and the dental, insurance, and education component are protective of all cause mortality. A one unit change in the log of the hazard ratio for any of these components controlling for all other components and covariates results in significantly increased survival. The primary care use and frequency component was slightly adverse to survival but close to the null value of one (HR = 1.051, 95% CI = 1.03 - 1.07). A one unit change in the log of the hazard ratio for the dental visit, insurance, and education component is significantly associated with increased survival. The age and gender covariates below the dashed line were adjusted for in the Cox model.

Figure 1 represents a Kaplan-Meier survival curve for all cause mortality with right censored data by tertiles of the risk score. The third tertile had the most favorable cumulative survival probabilities after 13 years (98%). The first tertile of the composite risk score had a lower cumulative survival probability after 13 years (72%).

DISCUSSION

Principal components Cox regression is a useful method for combining related predictors and can be applied to a more extensive list of socioeconomic status variables. Being able to afford health care services and prescription medicine is an important predictor of mortality. The

use of primary care and familiarity with such access also plays a role in survival. Interestingly, the accessibility to dental care, education, and insurance status component is significantly protective of mortality. A combination of components puts the focus on the importance of the tenets of a functional health care system, accessibility, cost, and quality. This demonstrates the relevance between overall health and oral health. Insurance and education were key players in survival outcomes. Imputed income, a major indicator of socioeconomic status is unsurprisingly related to mortality as it likely affects a number of unmeasured covariates that can be favorable to survival.

An important limitation to this study was the availability of socioeconomic status variables collected as part of the adult sample questionnaire. Additional inclusion of SES indicators such as accumulated wealth and occupation would add pertinent information to estimate the socioeconomic status construct. Being that the NHIS is a series of cross-sectional surveys, there is no ability to capture time varying SES indicators in order to better understand the time frame at which certain SES indicators change. The SES components used in the Cox proportional hazards model were limited to the time of the survey and thus, do not account for any long term changes in socioeconomic status.

This study benefitted from a large the sample size by combining across six years of NHIS data collection. NDI database linking is resourceful due to its comprehensive assessment of mortality status from death records year after year. SES groups that are protective of mortality warrant further investigation and can guide interventions for improving health outcomes at a broader scale. Existing literature supports the influence of education as a gradient for disease risk.[9] Future studies can focus on predetermined sets of related SES indicators that are most practical for intervention purposes.

Variable	Affordability of Care	Primary Care Use and Frequency	Dental, Insurance, & Education
Usual Care Location	0.165	0.833	0.105
Unable to afford in past 12 months			
Prescription Medicines	0.914	-0.026	0.184
Mental Health Care or Counseling	0.911	0.046	0.016
Dental Care	0.901	0.101	0.112
How long since last dental visit?	0.156	0.27	0.677
How long since last doctor visit?	-0.099	0.853	0.115
Insurance status (none, public, private)	0.429	0.405	0.545
Education	-0.004	-0.052	0.897

Table 1. Adult sample item loadings for proximal and distal measures of SES. Columns represent resulting components from the principal components analysis for categorical variables. Dark shading indicates component loadings greater than the 0.8. Lighter shading indicates values between 0.4 and 0.8.

Component	Hazard Ratio	Log HR	SE of Log HR	95% CI
Affordability of Care	0.881	-0.127	0.012	(0.86 - 0.90)
Primary Care Use & Frequency	1.058	0.056	0.011	(1.03 - 1.08)
Dental, Insurance & Education	0.788	-0.238	0.009	(0.77 - 0.80)
Income	0.826	-0.191	0.012	(0.81 - 0.85)
Age (M = 45)	1.086	0.083	0.001	(1.09 - 1.09)
Gender (Male)	1.598	0.469	0.017	(1.55 - 1.65)

Table 2. Multivariable survey Cox proportional hazards regression coefficients for SES components. Age and gender were controlled for in the model.

Socioeconomic indicators as predictors of all cause mortality in the United States

Hunter College School of Public Health

2180 Third Ave

New York, NY 10035

ABSTRACT

The theoretical social construct of socioeconomic status (SES) if often difficult to quantify. Attempts to define this construct result in commonly used indicators based on education, income, occupation and accumulated wealth. Despite this, there is no consistent collection of socioeconomic status indicators across population surveys. The aim of this study is to investigate related SES predictors from the National Health Interview Survey (NHIS) as drivers for all cause mortality. Leveraging linkage to the National Death Index (NDI) data, the time-to-event indicator was calculated for nearly all participants (94%). Principal Components Analysis (PCA) for categorical variables was used to identify a set of risk scores most associated with all cause mortality.A survey Cox proportional hazards regression was then used to create a composite risk score that was found to be predictive of all cause mortality. A Kaplan-Meier plot shows the predictive ability of the tertiles of the composite risk score. All composite scores were significantly influential influential to survival. The dental visits, insurance and education component had the greatest protective effect of the event compared to the other composite scores. This approach can be used to combine several SES indicators into one composite risk score.

INTRODUCTION

The theoretical constructs related to social status are based on a variety of indicators such as education, occupation, household income and accumulated wealth. These indicators are extensively studied under the umbrella term of socioeconomic status (SES). The effects of SES on health outcomes and in disparities research have been widely investigated alongside race/ethnicity.[1,2] However, due to the dynamic nature of SES, difficulty of collection, and lack of precision and reliability,[3] there is no agreement on a particular set of indicators for socioeconomic status in population surveys. Surveys like the Demographic and Health Survey have data-specific indices for measuring SES although this measure does not translate well into multiple countries with varying levels of wealth.[4] At least in the United States, there is no comprehensive set of indicators for SES that are routinely collected in population-wide surveys.[1,5] In 1997, Krieger and colleagues found that only two-thirds of the states included education level information of mothers in birth certificates and one-fourth of states published that of fathers.[6] The authors found no data was collected concerning income level for any of the national registries or certificates investigated at the time.[6] The latest Health, United States 2013 report prepared by the CDC contains important socioeconomic indicators like education, household poverty level and insurance status on the majority of tables presented.[7] Krieger and colleagues detailed the need for carefully considered measures of socioeconomic position that would account for concerns of privacy and confidentiality.[6]

Typically, research results report on the relationship between SES and an outcome of interest with little to no explanation on the mechanism of the effect.[3] Shavers makes a distinction between two types of SES measures: 1) compositional measures 2) contextual measures.[3] Compositional measures of SES focus on indicators that directly relate to the individual such as

occupation, education, and income and wealth. Contextual measures of SES are related to the individual's environment and can include measures of neighborhood, county, as well as census tract levels of SES.[3]

Shavers contends that contextual measures of SES often do not correlate well with individual measures of SES.[3] This is likely due to the generalization or aggregation of region characteristics in terms of SES levels. Contextual measures of SES are sometimes the only option for approximating SES at the aggregate level when such data is not available at the individual one.[8] Therefore, census data is often used to obtain an average measure of socioeconomic status at the tract level.[5]

It is important to note that individual measures of SES are not without flaws. Problems can arise when measures of SES in particular groups of people (e.g. retirees) do not reliably reflect the true SES, especially in measures of occupation.[1] Individual measures of education fail to capture on the job training opportunities, other personal capital investments made,[1] and shifts in the distribution of education. Household measures of income may not reflect accurate levels of SES if there is unequal access to household wealth.[1] Despite this, Duncan and colleagues support the use of household income as an optimal measure of SES for being more sensitive to changes in the SES and health relationship. Particularly, disposable income is a good indicator of standard of living and the life opportunities experienced.[1] Age, race-ethnicity and sex are known to vary in the distribution of SES indicators.[1] The literature on SES and mortality in the NHIS has shown the education gradient of risk among preventable and less preventable diseases.[9]

The literature tends to focus on individual compositional measures of SES, such as income, occupation, and education [1–3,9]. The present study aims to compare and combine groups of related individual SES indicators from the National Health Interview Survey (NHIS) in order

to create a single risk score for all cause mortality. These groups of SES indicators can be considered social drivers for all cause mortality within the scope of the NHIS and the linked National Death Index (NDI) dataset. In contrast to singular measures of SES, combinations of SES predictors can be more advantageous in predicting mortality. In turn, these sets of SES predictors can be further investigated in order to target and focus on modifiable risk factors.

METHODS

Data

The National Health Interview Survey (NHIS) is an ongoing cross-sectional survey conducted by the National Center for Health Statistics a division of the Center for Disease Control and Prevention (CDC). The NHIS monitors national health trends by asking participants about a wide range of health topics.[10] It is a nationally representative sample of noninstitutionalized adults, 17 years of age or over, residing in the United States via personal household interviews. The NHIS survey data was recently linked to mortality data from the National Death Index (NDI).[11] The mortality data linkage was done based on probabilistic matching of NDI records with NHIS survey data by the CDC up until the year 2011.[11] The publicly available data were be obtained from the CDC website (www.cdc.gov/nchs) and included survey years from 1998 to 2003 due to similar complex survey sampling strategies. In order to combine across years, survey weights were averaged by the number of years in the entire data thus, all weight estimates were divided by 6 for each year included in the data. All analyses were done using R statistical software (version 3.1.2).[12] The "survey" package written by Thomas Lumley and was used for adjusting for complex survey sampling. The "SAScii" and "readr" packages written by Anthony D'Amico and Hadley Wickham, respectively, were used to read and parse fixed width and SAS files downloaded from the CDC FTP website.

Data analysis plan

Widely used methods for dimension reduction are based on the principal component analysis (PCA) or factor analysis.[13] Separate PCA analyses were run each for (1) imputed income and poverty ratios and (2) for categorical variables related to health care access, utilization, insurance status and education. Imputed income variables included household income and poverty ratio, which were provided in the data. These variables were obtained from multiple imputation procedures (5 in total) by survey year. Pearson correlations were used to calculate the correlation matrix for the income and poverty ratio component. Kolenikov and colleagues highlight the consequences of using of discrete variables in PCA without the appropriate methodology.[14] Hence, polychoric correlations were used to create a correlation matrix to derive the principal components for these discrete categorical variables. Insurance status was a recoded variable derived from a combination of coverage status and private insurance coverage.

The time-to-event indicator was calculated from the linked mortality dataset simply by obtaining the difference between the year of death and the year the survey was administered. Participants without a valid year of death are assumed to be alive up until 2011, the last date of collection of mortality data, and were right censored. Mortality data was then merged to survey and income data by participant-level identification numbers.

The survival function was plotted using nonparametric Kaplan-Meier curves. Finally, a Cox Proportional Hazards model for survey data was used to build a model that included the extracted components from the PCA analyses controlling for age and gender.

Measures

Principal Components

Items under the first component describe the ability to afford health care services like

prescription medicines, mental health care, and dental care by asking, “During the past 12 months, was there any time when you needed any of the following but didn’t get it because you couldn’t afford it?” These items load highly and are part of the first component named “Affordability of Care.” The second component describes variables that are related to use and frequency of primary health care. Questionnaire items that load highly in this component ask, “Is there a place that you usually go to when you are sick or need advice about your health?” and “About how long has it been since you last saw or talked to a doctor or other health care professional about your own health?” The last component included dental health care use, insurance type and educational attainment. High loading questionnaire items in this component asked, “About how long has it been since you last saw or talked to a dentist? Include all types of dentists, such as orthodontists, oral surgeons, and all other dental specialists, as well as dental hygienists” and “What is the highest level of school you have completed or the highest degree you have received?” Detailed descriptions of the items included in the principal components are provided in Appendix I.

RESULTS

Merging with National Death Index records resulted in a loss of 6% of participants; thus, a total of 179,012 participants were included in the analyses. The mortality event occurred in 11.5 % of the survey sample with a standard error of 0.001. The survey adjusted mean age of the sample was 45 years with a standard error of 0.10. Fifty-two percent of the survey sample were female.

Table 1 shows the results of the principal components analysis based on select questions from the adult sample related to socioeconomic status. Variables with component loadings greater than 0.8 are shaded dark gray. Participants able to afford health care services and

prescription medicines score highly in the first component of affordability of care. Participants with a usual primary care location and who have recently seen their primary care provider score highly in the primary care use and frequency component. Participants with high education, private insurance status and recent dental visits score highly in the dental, insurance, and education component.

Table 2 shows the results of the survey Cox proportional hazards regression model that includes all components and covariates (including income, age, and gender). Affordability of care, income, and the dental, insurance, and education component are protective of all cause mortality. A one unit change in the log of the hazard ratio for any of these components controlling for all other components and covariates results in significantly increased survival. The primary care use and frequency component was slightly adverse to survival but close to the null value of one (HR = 1.051, 95% CI = 1.03 - 1.07). A one unit change in the log of the hazard ratio for the dental visit, insurance, and education component is significantly associated with increased survival. The age and gender covariates below the dashed line were adjusted for in the Cox model.

Figure 1 represents a Kaplan-Meier survival curve for all cause mortality with right censored data by tertiles of the risk score. The third tertile had the most favorable cumulative survival probabilities after 13 years (98%). The first tertile of the composite risk score had a lower cumulative survival probability after 13 years (72%).

DISCUSSION

Principal components Cox regression is a useful method for combining related predictors and can be applied to a more extensive list of socioeconomic status variables. Being able to afford health care services and prescription medicine is an important predictor of mortality. The

use of primary care and familiarity with such access also plays a role in survival. Interestingly, the accessibility to dental care, education, and insurance status component is significantly protective of mortality. A combination of components puts the focus on the importance of the tenets of a functional health care system, accessibility, cost, and quality. This demonstrates the relevance between overall health and oral health. Insurance and education were key players in survival outcomes. Imputed income, a major indicator of socioeconomic status is unsurprisingly related to mortality as it likely affects a number of unmeasured covariates that can be favorable to survival.

An important limitation to this study was the availability of socioeconomic status variables collected as part of the adult sample questionnaire. Additional inclusion of SES indicators such as accumulated wealth and occupation would add pertinent information to estimate the socioeconomic status construct. Being that the NHIS is a series of cross-sectional surveys, there is no ability to capture time varying SES indicators in order to better understand the time frame at which certain SES indicators change. The SES components used in the Cox proportional hazards model were limited to the time of the survey and thus, do not account for any long term changes in socioeconomic status.

This study benefitted from a large the sample size by combining across six years of NHIS data collection. NDI database linking is resourceful due to its comprehensive assessment of mortality status from death records year after year. SES groups that are protective of mortality warrant further investigation and can guide interventions for improving health outcomes at a broader scale. Existing literature supports the influence of education as a gradient for disease risk.[9] Future studies can focus on predetermined sets of related SES indicators that are most practical for intervention purposes.

Variable	Affordability of Care	Primary Care Use and Frequency	Dental, Insurance, & Education
Usual Care Location	0.165	0.833	0.105
Unable to afford in past 12 months			
Prescription Medicines	0.914	-0.026	0.184
Mental Health Care or Counseling	0.911	0.046	0.016
Dental Care	0.901	0.101	0.112
How long since last dental visit?	0.156	0.27	0.677
How long since last doctor visit?	-0.099	0.853	0.115
Insurance status (none, public, private)	0.429	0.405	0.545
Education	-0.004	-0.052	0.897

Table 1. Adult sample item loadings for proximal and distal measures of SES. Columns represent resulting components from the principal components analysis for categorical variables. Dark shading indicates component loadings greater than the 0.8. Lighter shading indicates values between 0.4 and 0.8.

Component	Hazard Ratio	Log HR	SE of Log HR	95% CI
Affordability of Care	0.881	-0.127	0.012	(0.86 - 0.90)
Primary Care Use & Frequency	1.058	0.056	0.011	(1.03 - 1.08)
Dental, Insurance & Education	0.788	-0.238	0.009	(0.77 - 0.80)
Income	0.826	-0.191	0.012	(0.81 - 0.85)
Age (M = 45)	1.086	0.083	0.001	(1.09 - 1.09)
Gender (Male)	1.598	0.469	0.017	(1.55 - 1.65)

Socioeconomic indicators as predictors of all cause mortality in the United States

Hunter College School of Public Health

2180 Third Ave

New York, NY 10035

ABSTRACT

The social construct of socioeconomic status (SES) if often difficult to quantify. Attempts to define this construct result in commonly used indicators based on education, income, occupation and accumulated wealth. Despite this, there is no consistent collection of socioeconomic status indicators across population surveys. The aim of this study is to investigate related SES predictors from the National Health Interview Survey (NHIS) as social drivers for all cause mortality. Leveraging linkage to the National Death Index (NDI) data, the time-to-event indicator was calculated for nearly all participants (94%). Using Principal Components Analysis (PCA), socioeconomic status indicators related to affordability of prescriptions and health care services tended to correlate highly with each other. Indicators related to access to care, gender, and having a usual place of care were also correlated. Having access to dental care was differentiated from having access to primary care and resulted as a separate component in the analysis. Results from the survey Cox proportional hazards regression show that access to both primary and dental care, as well as the affordability of such care, are all important predictors associated with mortality.

INTRODUCTION

The theoretical constructs related to social status are based on a variety of indicators such as education, occupation, household income and accumulated wealth. These indicators are extensively studied under the umbrella term of socioeconomic status (SES). The effects of SES on health outcomes and in disparities research have been widely investigated alongside race/ethnicity.[1,2] However, due to the dynamic nature of SES, difficulty of collection, and lack of precision and reliability,[3] there is no agreement on a particular set of indicators for socioeconomic status in population surveys. Surveys like the Demographic and Health Survey have data-specific indices for measuring SES although this measure does not translate well into multiple countries with varying levels of wealth.[4] At least in the United States, there is no comprehensive set of indicators for SES that are routinely collected.[1,5] In 1997, Krieger and colleagues found that only two-thirds of the states included education level information of mothers in birth certificates and one-fourth of states published that of fathers.[6] The authors found no data was collected concerning income level for any of the national registries or certificates investigated at the time.[6] The latest Health, United States 2013 report prepared by the CDC contains important socioeconomic indicators like education, household poverty level and insurance status on the majority of tables presented.[7] Krieger and colleagues detailed the need for carefully considered measures of socioeconomic position that would account for concerns of privacy and confidentiality.[6]

Typically, research results report on the relationship between SES and an outcome of interest with little to no explanation on the mechanism of the effect.[3] Shavers makes a distinction between two types of SES measures: 1) compositional measures 2) contextual measures.[3] Compositional measures of SES focus on indicators that directly relate to the individual such as

Commented [JD1]: In what context do you mean? Public health studies?

Commented [JD2]: They are only really considered compositional in the context of neighborhood effects. Otherwise they are individual-level effects.

occupation, education, and income and wealth. Contextual measures of SES are related to the individual's environment and can include measures of neighborhood, county, as well as census tract levels of SES.[3]

Shavers contends that contextual measures of SES often do not correlate well with individual measures of SES.[3] This is likely due to the generalization or aggregation of region characteristics in terms of SES levels. Contextual measures of SES are sometimes the only option for approximating SES at the aggregate level when such data is not available at the individual one.[8] Therefore, census data is often used to obtain an average measure of socioeconomic status at the tract level.[5]

It is important to note that individual measures of SES are not without flaws. Problems can arise when measures of SES in particular groups of people (e.g. retirees) do not reliably reflect the true SES, especially in measures of occupation.[1] Individual measures of education fail to capture on the job training opportunities and other personal capital investments made.[1] Household measures of income may not reflect accurate levels of SES if there is unequal access to household wealth.[1] Despite this, Duncan and colleagues support the use of household income as an optimal measure of SES for being more sensitive to changes in the SES and health relationship. Particularly, disposable income is a good indicator of standard of living and the life opportunities experienced.[1] Age, race-ethnicity and sex are known to have differential effects on the measurement of SES.[1]

The present study aims to extract groups of related SES indicators from the National Health Interview Survey (NHIS) and to describe sets of indicators that are social drivers for all cause mortality within the scope of the NHIS by using the National Death Index (NDI) linked data. And what is the goal? To better understand which SES indicators should be intervened on,

Commented [JD3]: Perhaps, but it can also be a better measure because it is less noisy than individual measures and thus smooths out measurement error.

Commented [JD4]: And the distribution of educational attainment has changed dramatically over time so it doesn't always mean the same thing.

Commented [JD5]: What do you mean by "effects on the measurement of?"

or is this completely predictive modeling without any causal framework? What gap in the literature is this paper hoping to fill? Any discussion of previous literature on SES and mortality using NHIS and how this fits in?

METHODS

Data

The National Health Interview Survey (NHIS) is an ongoing cross-sectional survey conducted by the National Center for Health Statistics a division of the Center for Disease Control and Prevention (CDC). The NHIS monitors national health trends by asking participants about a wide range of health topics.[9] It is a nationally representative sample of noninstitutionalized adults, 17 or over, residing in the United States via personal household interviews. Mortality data from the National Death Index (NDI) was recently linked to the NHIS survey data which was obtained until the year 2006.[10] Mortality data linkage was done based on probabilistic matching of NDI records with NHIS survey data by the CDC up until the year 2011.[10] The publicly available data were be obtained from the CDC website (www.cdc.gov/nchs) and included survey years from 1998 to 2003 due to similar complex survey sampling strategies. In order to combine across years, survey weights were averaged by the number of years in the entire data thus, all weight estimates were divided by 6 for each year included in the data. All analyses were done using R statistical software (version 3.1.2).[11] The "survey" package written by Thomas Lumley and was used for adjusting for complex survey sampling. The "SAScii" and "readr" packages written by Anthony D'Amico and Hadley Wickham, respectively, were used to read and parse fixed width and SAS files downloaded from the CDC FTP website.

Commented [JD6]: 2006 or 2011? Not consistent with previous sentence.

Data analysis plan

Widely used methods for dimension reduction are based on the principal component

analysis (PCA) or factor analysis.[12] Separate PCA analyses were run each for (1) imputed income and (2) categorical variables related to health care access and utilization (including gender). Imputed income variables included household income and poverty ratio. These variables resulted from multiple imputation (5 in total) procedures for each survey year and were already included in the data. Pearson correlations were used to calculate the correlation matrix for the income component. Kolenikov and colleagues point out that the use of discrete variables in PCA requires different methodology.[13] Polychoric correlations were used to create a correlation matrix in order to calculate the principal components for discrete categorical variables.

Commented [JD7]: What is the justification for this?

Commented [JD8]: What about other SES variables? Education? What else are you using? Not clear here—all of your measures/variables should be described very specifically.

The time-to-event indicator was calculated from the linked mortality dataset simply by obtaining the difference between the year of death and the year the survey was administered. Participants without a valid year of death are assumed to be alive up until 2011, the last date of collection of mortality data, and were right censored. Mortality data was then merged to survey and income data by participant-level identification numbers.

The survival function was plotted using the nonparametric Kaplan-Meier method. Finally, a Cox Proportional Hazards model for survey data was used to build a model that included the extracted components from the PCA analyses.

RESULTS

Merging with National Death Index records resulted in a loss of 6% of participants; thus, a total of 179,012 participants were included in the analyses. The mortality event occurred in 11.5 % of the survey sample with a standard error of 0.001. Using survey weights, the mean age of the survey sample was 45 years of age with a standard error of 0.10. The majority of participants were female (52 %).

Table 1 shows the results of the principal components analysis based on select questions from the adult sample related to socioeconomic status. Variables with high principal component loadings are shaded gray. Items shaded under the first component describe the inability to afford health care services like prescription medicines, mental health care, and dental care by asking, "During the past 12 months, was there any time when you needed any of the following but didn't get it because you couldn't afford it?" These items load highly and are part of the first component called "Affordability." The second component resulting from the PCA describes variables that are related to access and familiarity to primary care. Questionnaire items in this component ask, "Is there a place that you usually go to when you are sick or need advice about your health?" and "About how long has it been since you last saw or talked to a doctor or other health care professional about your own health?" Interestingly, gender also loaded moderately to this component. The last component included a single item that was differentiated from the rest, this item asked, "About how long has it been since you last saw or talked to a dentist? Include all types of dentists, such as orthodontists, oral surgeons, and all other dental specialists, as well as dental hygienists."

Commented [JD9]: Describe all of this in your measures section, not results.

Table 2 shows the results of the survey Cox proportional hazards regression model that includes all components and covariates (including the income component and age). Affordability, primary care, and income components are protective of all-cause mortality. A one unit change in the log of the hazard ratio for any of these components controlling for all other components results in significantly increased survival. Both the dental visits component and age were adverse to survival. A one unit change in the log of the hazard ratio for the dental visit component is significantly associated with decreased survival. As expected, a one unit change in age was significantly associated with decreased survival.

Figure 1 represents a Kaplan-Meier survival curve for all cause mortality with right censored data. The vast majority of participants had favorable cumulative survival probabilities. A little less than 90% of participants survived after 12 years from the year of survey administration.

DISCUSSION

Principal components cox regression is a useful method for combining related predictors and can be applied to a more extensive list of socioeconomic status variables. Being able to afford health care services and prescription medicine are important predictors of mortality. The level of access to primary care and familiarity with such access also play a role in survival. Interestingly, accessibility to dental care is also an important predictor of mortality. This highlights the importance of oral health and its relationship to overall health as a key player in survival outcomes. Imputed income, a major indicator of socioeconomic status is unsurprisingly related to mortality as it likely affects a number of unmeasured covariates that can be favorable to survival. Why no data for educational attainment? This is one of the most important SES predictors in the literature.

Commented [JD10]: What is the reasoning here…i.e. what underlying mechanism is this tapping into? A bit of a leap to attribute this directly to oral health.

An important limitation to this study was the availability of socioeconomic status variables collected as part of the adult sample questionnaire. Indicators of race-ethnicity, insurance status, and employment status would add pertinent information to estimate the socioeconomic status construct. The indicators used in the Cox proportional hazards model were recorded at the time of the survey and thus, do not account for any changes in overall socioeconomic status over time.

Commented [JD11]: I'm quite certain these variables are available in the NHIS.

This study benefitted from a large the sample size by combining across six years of NHIS data collection. NDI database linking is resourceful as this collection of data is comprehensive in

its assessment of mortality status from death records year after year. Future studies should focus on more expansive sets of predictors that try to capture the essence of socioeconomic status.

Both the introduction and discussion could use a lot more justification for this analysis and implications for overall research in this area. How is this type of analysis helping us to understand the mechanism linking SES and health beyond the many studies that have predicted mortality with SES variables previously? What is the value added to this approach? How does this support or contradict existing literature? As currently described the motivation and implications are not clear.

Table 1. Sample Adult Items Loadings

Variable	Affordability	Primary Care Access	Dental Visits
Gender	-0.173	**0.695**	0.124
Having usual care location	0.279	**0.763**	-0.071
Unable to afford in past 12 months			
Prescription medicines	**0.920**	-0.052	-0.107
Mental health care or counseling	**0.911**	0.005	-0.028
Dental care	**0.906**	0.064	-0.124
How long since last dental visit?	-0.146	-0.1	**0.954**
How long since last doctor visit?	0.037	**-0.736**	0.288

Table 2. Cox Proportional Hazards Regression Coefficients

Component	Hazard Ratio	Log HR	SE of Log HR	95% CI
Affordability	0.931	-0.072	0.013	(0.91 - 0.95)
Primary Care Access	0.884	-0.123	0.009	(0.87 - 0.90)
Dental Visits	1.138	0.129	0.007	(1.12 - 1.15)
Income	0.787	-0.239	0.011	(0.77 - 0.81)
Age (M=45, SE=0.1)	1.088	0.084	0.001	(1.09 - 1.09)

Commented [JD12]: Does this go in the opposite direction or is it coded differently?

Abstract (243 words)

Objective: To develop a supplemental Woman Infants and Children (WIC) prenatal program pilot for foreign-born Hispanic women within a New York City Health and Hospitals Corporation (HHC) center to reduce excessive gestational weight gain associated with increasing length of stay in the United States (U.S.).

Methods: The New York Sharing Healthy Information Necessary for Empowering Society (SHINES!) Program will recruit ten foreign born Hispanic mothers with a length of stay in the U.S. of at least 5 years. Participants must be less than 4 weeks of gestation as the program's launch in the Metropolitan Hospital Center WIC site. The program will meet once a month for 8 months between October 15th, 2015 and June 30th, 2016.

Results: Program activities will consist of four nutrition sessions that will focus on fundamental nutrition objectives while, educating participants on EGWG and the effects of acculturation on pregnancy. Three follow up meetings will provide one-on-one nutrition consultation with staff and a closing graduation ceremony to celebrate successful participant completion of program.

Conclusions: The program will aid in increasing participant understanding of potential negative influences of EGWG and urge the preservation of home-country diets among foreign-born Hispanics. New York SHINES! seeks to expand the supplemental nutrition program by implementing the program in all WIC sites located in New York City Health and Hospitals Corporation facilities serving high volumes of foreign-born Hispanics. The program encourages the national WIC program to modify current nutrition curriculum to target all foreign-born consumers.

Introduction

Excessive gestational weight gain (EGWG) is the occurrence of weight gained during pregnancy superseding recommendations set by the Institute of Medicine (IOM; Einerson, 2011). On average, a woman weight gain during pregnancy should not exceed 20 lbs if her pre-pregnancy BMI is >30 kg/m^2. Most prenatal weight gain occurs among women with a BMI >30 kg/m^2 (Einerson, 2011; Figure 1). Einerson found that 30 percent (%) of women within reproductive age (13 to 44 years of age) were classified as obese (Einerson, 2011). Excessive amounts of weight gained during pregnancy heighten maternal and infant risks of developing gestational diabetes, premature birth, abnormal birth weight, infant respiratory and neurological complications and caesarean sections (Einerson, 2011).

In a study of EGWG in Southern California, 30% of bilingual Hispanic women gained more weight than the IOM recommendations compared to 18.5% of Hispanic women who only spoke Spanish (Koleilat, 2013). The latter suggests that acculturation may be linked to EGWG among foreign-born mothers (Callister, 2002). In as little as five years, individuals incorporate less nutritional foods because of lack of nutrition education, linguistic isolation, neighborhood characteristics or income (Martinez, 2013). Less acculturated mothers are more likely to eat the host country foods as the length in the United States (U.S.) increases (Callister, 2002). For instance, Martinez found that as years in the U.S. increase, women are twice as likely to include foods with higher fat content including fast food and snacks and less likely to consume fruits and vegetables (Martinez, 2013).

To my knowledge, there are no current interventions specific to the excessive gestational weight gain among prenatal foreign-born Hispanic women living in the U.S. however, an intervention program called Viva Bien! addressed the influence of acculturation on effective self

management of diabetes among Latinas (Barrera, 2012). Upon the program's completion evaluators, assessed the effectiveness of cultural adapted diabetes prevention program for foreign born Hispanic women in which was originally intended for a Caucasian audience (Barrera, 2012). Viva Bien! succeeded at guiding participants in adjusting their lifestyle to reduce diabetes complications and the development of coronary heart disease. Over a period of 12 months, the attendance rates of the intervention ranged from 48% to 58%, a positive indicator of an effective program. Because of the intervention, participants suffering from Type II diabetes were able to decrease their hemoglobin Ac1 percentages and efficiently manage their blood sugar levels.

In recent years, New York City has experienced an influx of Hispanics migrating to the area. Program planners saw this group as ideal for a cultural based nutrition pilot seminar to encourage cultural preservation as length in the United States increases. In 2011, Latin countries represented the largest migration to New York City with 32% (City of New York, 2013). Thus, the objective of the project is to develop a supplemental Woman Infants and Children (WIC) prenatal program pilot for foreign-born Hispanic women within a New York City Health and Hospitals Corporation (HHC) center to reduce excessive gestational weight gain associated with increasing length of stay in the United States.

Methods

The New York Sharing Healthy Information Necessary for Empowering Society (SHINES!) Program will recruit ten Hispanic mothers born outside the United States with a length of stay of at least 5 years and within 4 weeks of gestation. The program will be launched at the Metropolitan Hospital Center WIC site located on the Upper Eastside of Manhattan. This program will take place within a high volume WIC location, East Harlem, where 80% of

participants are foreign-born Hispanic mothers. A WIC location is ideal because the staff have direct contact with members of the target community maximizing the level of impact. This program will be an enhanced extension of the current WIC appointments.

The Women Infants and Children program (WIC) is a forty-year-old nutrition entity that services prenatal and interconceptional (in between pregnancy) women with children up to 5 years of age (New York State Department of Health, 2014). WIC's mission encourages families to make smart nutritional choices while incorporating regular physical activity to reduce obesity in the United States (New York State Department of Health, 2014). Women who meet national Medicaid guidelines are eligible to partake in the program and receive WIC vouchers that are based on the mother's option to breastfeed (New York State Department of Health, 2014). The vouchers allow families to purchase WIC approved foods (milk, cereal, fruit, etc.) that are low in fat while, high in nutrients (New York State Department of Health, 2014). Through WIC, families will have access to nutritionists who will facilitate nutrition education and techniques (e.g. portion control). In addition, WIC provides breastfeeding peer counselors who assist in breastfeeding trouble shooting in an intimate setting (New York State Department of Health, 2014). New York SHINES! will supplement the existing WIC program by including items of ethnic and cultural identity to fortify the impact of the longstanding program's mission to reduce obesity, malnutrition and food insecurity among low-income households.

During recruitment, thirty women will be screened for eligibility, compliance or interest in the program (Figure 2). Upon receiving medical clearance from the participant's primary care physician, assigned members of the WIC staff will attempt to invite eligible mothers to participate in the program via telephone. A formal invitation that will reiterate program logistics (date, location and time) indicated during the phone call will be mailed to the addresses stored in

WIC electronic database (WICSIS). Participants will meet once a month for 8 months between October 15th, 2015 and June 30th, 2016. Mothers will be engaged during their one-on-one WIC nutrition consultation. Prospective participants will be asked to complete a brief questionnaire (Appendix 1) in which would serve as a screening tool. The questionnaire will require potential participants to disclose details such as birth country, time in U.S. and current weight. The information derived from the questionnaire will provide the tools needed to tailor the delivery of content thus, increasing the effectiveness of the intervention.

Selected participants will be engaged during 8 months in a nutrition education program comprised of 8 sessions centering on preserving traditional food and diet while incorporating weight management as it relates to the prevalence of gestational obesity as a mother's years in the United States increase. The staff/facilitators for the SHINES! program will utilize WIC personnel and will consist of two registered dietitians responsible for health education and support group monitoring, three nutritionist assistants responsible for maintaining participant records and two community health workers from the hospital's community outreach division. The community health workers will be available after each session to conduct case management for any participant who will need referrals/information for services such as temporary Medicaid, or immigration.

Results

The nutrition education curriculum will be as followed: Session 1 "Prenatal Weight-Gain and the Effect on Your Baby", Session 2 "Health & Heritage: A Guide to Preserving the Diet from Your Home Country", Session 3 "Mantener las Papas! - To Hold or to Keep the Potatoes!" A Guide to Portion Control & Favorite Traditional Foods", Session 4 "Navigating the

Supermarket: How to Pick the Best Produce & Where to Find Food Brands from Your Home-Country". Sessions 5-7 will be designated for follow up meetings where mothers can have one-on-one weight management consultation. Lastly, Session 8 will serve as a program wrap up and graduation (Figure 3). Sessions will be scheduled the first Wednesday of every month for 1.5 hours from 12 pm-1:30 pm. The desired total of participants for the program will be ten women who are currently enrolled in the hospital's WIC program. The 8 month series will occur separately from the regularly scheduled WIC health education classes. Roundtrip metro cards will be provided to the mothers for every session to alleviate travel expenses.

The program orientation will occur one hour before the official start of the nutrition curriculum activities. During this time, mothers will be acquainted with the New York-SHINES! staff and other program's participants. The group at large will be participating in icebreaker activities including the thumb-ball question and answer activity to set the tone for the duration of the program. The questions will range from favorite colors and foods to what prompts the moms to smile.

Concurrently with the icebreaker portion of the orientation, a WIC registered dietician provides the mother with an overview of the program and its intensions for providing her an opportunity to live a healthy life thus setting the foundation for her baby's healthy start. A consent form will be provided to solidify the mother's understanding of her involvement and acknowledgement that she may withdraw from the program at any point in time. Once all the participants complete their first SHINES! consultation, facilitators will administer a brief pretest that will consist of 4 questions (Appendix 2) on healthy eating and the effects of prenatal weight gain to measure the mother's level of understanding surrounding the matter of diet and nutrition.

Session 1 "Prenatal Weight-gain and the Effect on Your Baby" will address the exact effects of obesity during pregnancy, and the possible effects on both the mother (gestational diabetes) and infant's health (adult obesity, adverse birth outcomes). Nutritionists will dispel myths about "eating for two" and will suggest healthy snacks to satisfy cravings using WIC approved foods. The curriculum calls for addressing the IOM pregnancy weight gain recommendation guidelines (figure 1). The mothers will learn how their pre-pregnancy weight will determine the increments in which she can gain during pregnancy.

Session 2 "Health & Heritage: A Guide to Preserving the Diet from Your Home Country" will consist of educating the mothers on the significance behind continuing culinary traditions here in America. The mothers are provided with the opportunity to connect the preservation of family recipes and their quality of life. The session will begin by asking participants to share their favorite meals from back home and if they brought the recipes to America. Facilitators will discuss the science behind acculturation and its effect on health. Participants will learn what acculturation may mean for both her and her infant.

Session 3 "Mantener las Papas! - To Hold or to Keep the Potatoes?" A Guide to Portion Control & Favorite Traditional Foods" will encompass the significance behind portion control and traditional dishes. The SHINES! staff will educate participants on the importance of portion control using the "Choose My Plate" campaign recommendations (figure 4). In some cultures, carbohydrates and starches (e.g. potatoes, rice) are key components of meals. This session will call for participants to look closely at the food groups presented on their plates and the amount. The mothers will learn that although they may opt to continue their culinary traditions from their home countries portion control habits remain crucial in body functioning and weight management. The portion control topic will segue into a deep discussion of how an

overindulgence of processed foods and snacks containing high levels of sodium and saturated fat can lead to high blood pressure, high cholesterol and other negative health effects.

Session 4 "Navigating the Supermarket: How to Pick the Best Produce & Where to find Food Brands from Your Home-Country" will incorporate the use of WIC checks, Supplemental Nutrition Assistance Program (SNAP) vouchers and navigating around the supermarket. The first half of the session will take place at an Associated Supermarket within walking distance of Metropolitan Hospital. All foods acquired by SHINES! Participants have met nutritional standards for promoting optimal health for families. Here is where participants will be exposed to not only WIC approved foods but the availability of cultural product options. This session will provide the mothers with the tools to become privy to the set-up of the supermarket that draws attention to non-nutritious foods not conducive to reducing morbidity and mortality. Some of the supermarket tips would include understanding that junk food items commonly are highly visible at the beginning and end of every aisle. During the second portion of the session, the mother will participate in a discussion with program facilitators on where to find common brands from their countries of origin. Program staff will use a flip chart to write down vendor details. Following the session participants will receive handouts of local retailers that stock foreign brands vital to creating traditional dishes.

Sessions 5-7 will consist of follow up meetings with the New York SHINES! staff where mothers can individually meet to discuss her progress on making healthier food choices, preserving cultural diets from the home country and maintaining a healthy prenatal weight. Participants are encouraged to partake in a support group to discuss and share how they are integrating the information obtained during the nutrition instruction into their dietary practice. It

is important to note that for graduation each participant must attend at least one of the follow up meetings.

Session 8 will serve as a graduation and baby shower. The first 30 minutes will consist of staff administering a post-test (appendix 2) to measure increases in knowledge on excessive gestational weight gain upon program completion. The mothers will be informed of the amount of weight gained and loss during the program. Following the post-test will be a 30-minute discussion on their experiences while in the program. During this time program staff will encourage participants to share how they have incorporated lessons learned into their everyday lives. Metropolitan Hospital's auditorium will be adorned with flowers and other décor to celebrate the participant's completion of the program. The mothers will be able to invite a guest to share their special moment. As each participant is called, she will receive a certificate of completion.

Immediately following the 30 min graduation will be the baby shower with a lunch and traditional baby shower gifts. Because by the 8th month mark many mothers will be nearing their expected date of delivery, the program will provide strollers with detachable car seats as a gift. During the baby shower, the moms will learn that they will also be receiving cribs. Participants will have the crib delivered to a preferred address.

Results from the pre and post-tests will assess the effectiveness of the program and, any behavioral changes among the target population.

Conclusions/Discussion

New York SHINES! is designed to recognize the significance of preserving the cultural diets of Hispanic women born outside of the United States to reduce excessive weight

gain during pregnancy. As an extension of Women, Infants and Children program New York SHINES! will use culturally modified nutrition curriculum to ensure the healthy start of future Americans. Through its program objectives, New York SHINES! will decrease the frequency of infant morbidity including: abnormal birth weights, neurological and respiratory complications, premature birth and cesarean sections. The program will aid in increasing participant understanding of potential negative influences of EGWG during pregnancy and post-delivery through a series of nutrition education modules that will dispel myths such as "eating for two". Participants will be encouraged to continue to prepare traditional foods while actively preventing prenatal obesity. Introducing simple nutrition practices such as portion control, participants become champions in their own health.

New York SHINES! will foster a series of supportive of networks within WIC staff and among other participants. Such relationships will provide a safety net for foreign-born women who may reside in the U. S. alone or are unmarried. Through the cultivation of such alliances, participants will obtain accountability partners that will buffer the impact of acculturation. New York SHINES! operates as a resource for families to find solutions to obstacles that can potentially deter optimal health. In addition to connecting participants to entities like SNAP and emergency Medicaid enrollments New York SHINES! assist in culinary tradition preservation by identifying local retail sources that carry foreign brands. In 2014 nearly 40% (80 million) of the American public was categorized as obese (Ogden, 2014). New York SHINES! hopes to add a modern twist to the nation's ever changing demographics to continue to fortify the mission, visions and goals of WIC and similar programs.

A small sample size of ten (10) participants and the use of a single WIC location are limitations for the New York SHINES program. This culturally tailored nutrition program catered to prenatal foreign-born Hispanic women is not generalizable throughout other New York City Hispanic neighborhoods. For purposes of replicating New York SHINES! program planners would be careless to assume that all Hispanic subgroups share the same cultural customs. In the same respect program planners cannot presume that the social and economic determinants related to health presented with a Mexican population is the same determinants found within Dominican or Guatemalan communities. Such a small sample size will unsuccessfully represent the cultural variations among the targeted population. To encompass the array of countries represented within New York City extensive cultural research is crucial for program tailoring. Expanding New York SHINES! to other WIC locations with high volumes of foreign born Hispanic women will require program planners to study the cultural customs of targeted communities with the intention of creating appropriate curriculum.

The use of a WIC department that employs supremely educated nutrition staff members whom already developed a rapport with prospective participants is a strength of New York SHINES! The established WIC program at Metropolitan Hospital serving as the foundation for New York SHINES! provided a wealth of expertise on the subject of nutrition and the characteristics of the surrounding community. Knowledge of the community's characteristics were included in any cultural research conducted. The WIC program was ideal for program outreach and retention efforts because a captive audience was readily available. This additional benefit made participant recruitment much simpler. Nutritionists in whom they have developed relationships thus alleviating anxieties about participating in the program recruited mothers. Published reports specified that new Americans viewed the assortment of health educators as

"experts" in their field. (Patil, 2009). As result, foreign-born individuals are more likely to be receptive to public health messaging that will encourage behavioral adjustments for optimal health (Patil, 2009). Lastly, the nutrition education curriculum used for the 8 month program was derived from an existing WIC curriculum, with modifications to include items ethnic identity.

Recommendations

Based on the activities of this program the following recommendations are proposed:

- Expand the supplemental nutrition program by implementing the program in all WIC sites located in New York City Health and Hospitals Corporation facilities serving high volumes of foreign-born Hispanics.
- Enhance nutrition curriculums to incorporate items of ethnic and cultural identity to fortify the impact of the program's mission to reduce the risk of malnutrition, obesity and food insecurity amongst low-income households.

Public Health and Policy Implications

Encourage the national WIC program to modify current nutrition curriculum to target all foreign-born consumers of the program and strengthen the program's impact of reducing adverse effects of malnutrition and food insecurity. The forty-year-old entity will consistently adjust its nutrition education curriculum to reflect evolving demographic trends in United States. This action will assist the national program in strengthening obesity prevention during pregnancy by acknowledging the diversity that exists within their clientele.

The presence of New York SHINES! will create awareness of supportive services within the community such as the WIC theough referrals for care coordination to serve as solutions to

obstacles that may deter families from maintaining cultural identity as length of stay in the United States increases. New York SHINES essentially, a specialized WIC nutrition component exposes participants to resources to solve multiple social economic issues (i.e. food insecurity) through its program activities. Upon graduation, participants will have knowledge of processes such as food stamp enrollment in addition to where to purchase favored food brands from their home countries. Cohorts of the New York SHINES program have the opportunity to build social support networks among themselves. Members of the cohorts who were exposed to the same dosage of nutrition education can help each other maintain the principles and behavior modifications promoted during the 8th month program well after it concludes.

Participant Questionnaire

What is your age range? (Please circle all that apply)

18-24 25-30 35-40 40+

What is your birth country?

_____

What language do you feel most comfortable in? (Please circle all that apply)

English Spanish Cultural Dialect

How tall are you? _____ **How much do you weigh?** _____

When is your due date? _____

What are your top three favorite traditional dishes to cook?

1. _____
2. _____
3. _____

In what ways are you active? (Please circle all that apply)

Walking Jogging Dancing No activity

Do you live alone in the country? (Please circle all that apply)

Yes No

Would you like more support from women in your community to feel more comfortable in America? Please explain why.

Yes Explanation: _____

No Explanation: _____

In getting ready for your baby, do you have the means to get a stroller/car seat and a crib?

Yes No

Appendix 2

Prenatal Obesity Pre-Test

Name: _____ Date: _____

1. What is obesity?

___ High blood sugar ___ the inability to sleep

___ weighing more than recommended weight ___ weighing less than recommended weight

2. What are the causes of Obesity? (Check all that apply)

____Eating high calorie foods ____ drinking more juice than water

____ Lack of sleep ____ Stress

_____ Lack of exercise ____ Lack of money

3. What can obesity during pregnancy do to your baby? (Check all that apply)

____ Earlier delivery ____ Low birth weight

____ Underdeveloped organs ____ less chances for breastfeeding

1. True or False: As long as I am eating my traditional dishes from home, I can eat large portions of it because it is healthier than junk food?

____ True _____False

Prenatal Obesity Post-Test

Name: _____ Date: _____

4. What is obesity?

___ High blood sugar ___ the inability to sleep

Appendix B- Questionnaire 20

Abstract

Objective: To develop a questionnaire to assess the knowledge, skills, attitude, and awareness among nursing regarding cultural competence staff at Jacobi Medical Center from January 2nd through May 1st 2014.

Methods: Information on cultural practices and beliefs for the top six patient populations treated at Jacobi Medical Center was obtained from PubMed and anthropological textbooks. This information was used to develop a one-hour PowerPoint presentation. A pre-post questionnaire was developed using some questions adapted from the Clinical Cultural Competence Questionnaire including information on demographic, knowledge, skills, attitude, and awareness of cultural competency. This questionnaire will be given to participants before and after the PowerPoint presentation to assess their cultural competence.

Results: The questionnaire consists of 19 questions, ten out of the 19 questions were adapted from the Clinical Cultural Competence Questionnaire. It focuses on demographics, level of cultural competence, self- graded attitude, skills, knowledge toward socio-cultural issues as well as awareness of one's own identity, stereotype, prejudice, and bias. The questionnaire will assess nursing staff's cultural competence regarding knowledge, skills, attitude, and awareness of racial/ethnic minority patients' needs.

Conclusions: The questionnaire will be an important instrument to identify the strengths and weaknesses on cultural competence among nursing staff and to target specific domain for cultural competence intervention. It can be used for periodic assessment to track and monitor the level of cultural competence over time. Development of an instrument to measure patient's outcomes as a result of having cultural competence nursing staff should be the focus for future study.

Introduction

The United States (U.S.) has a diverse racial/ethnic population with over one third of the population (35.6%) identifying with racial/ethnic minority groups (U.S. Census Bureau 2013). In fact, minorities are projected to comprise 57% of the U.S. population by 2060 (U.S. Census Bureau 2012). Racial/ethnic diversity is pronouncedly observed in New York City (over 66% of the population belongs to racial/ethnic minority groups; U.S. Census Bureau 2010) and the Bronx (racial/ethnic minority groups represent over 90% of the population; U.S. Census Bureau 2013). As the U.S. population becomes more diverse, health care providers will see more patients presenting with different perspectives and beliefs related to health (Betancourt, Green, Carrillo, Park 2005). These differences may influence patients' adherence to their health care providers' recommendations (Berger 1998). To provide quality care to the growing racial/ethnic minorities, it is critical for health care providers to be cultural competent.

The cultural conflict between health care providers and racial/ethnic minority patients has resulted in a lower quality of care for minority population as compared to white Americans (Reynolds 2004), even when controlling for insurance affordability and financial stability (Institute of Medicine 2002). When health care providers possess the knowledge about their patients' racial/ethnic backgrounds, a better quality of care is likely to be provided (Stewart 1995). Research has shown that when there is a concordant physician-patient relationship, especially for minorities, there is a higher report of patient satisfaction, more adherence to medical recommendations, and better quality of care (Saha, Komaromy, Koepsell, Bindman 1999). Hence, cultural competence is important for clinicians to make proper diagnosis, to improve patient's adherence to medical treatment, and to have better health outcomes (Juckett 2005).

Recognizing the cultural competence of health care providers as one of the major factors to prevent and reduce racial/ethnic health disparities, the Institute of Medicine (IOM) had recommended cultural competence training for health care providers, focusing on their knowledge, skills, and attitudes toward treating racial/ethnic minority patients (Institute of Medicine 2002). As a requirement for medical school accreditation, cultural competence education is required as part of the medical school curriculum (Betancourt, Green, Carrillo, Park 2005). Some State Board of Medical Examiners, such as the ones from New Jersey, California, Connecticut, Washington, and New Mexico, require cultural competence training as part of the continuing medical education (Like 2011). The latter is necessary to provide quality of care for diverse racial/ethnic populations. In fact, there is strong evidence that cultural competence training has positive impact on health care providers' knowledge, skills, and attitudes toward racial/ethnic minorities' health needs (Beach et al., 2005).

Registered nurses, as first responders among health care providers, represent the largest portion (over 3 millions) of the U.S. health care professional workforce (U.S. Department of Health and Human Services 2010). They are the eyes and ears of the medical team in which they treat, report, and document racial/ethnic minority patients' interaction and feedback (Euromed Info 2014). However, according to the 2008 National Sample Survey of Registered Nurses, racial/ethnic minority registered nurses are underrepresented making up only 16.8% of the total registered nurse population (U.S. Department of Health and Human Services 2010). It is important for registered nurses to be cultural competent because they would have the first encounter with patients, do initial examination, and spend time, more than any physicians, in taking care of racial/ethnic minority patients when they admitted into the hospital. Therefore, this study aims to develop a questionnaire to assess the knowledge, skills, attitude, and

awareness among nursing regarding cultural competence staff at Jacobi Medical Center from January 2nd through May 1st 2014.

Methods

I conducted a literature search to inquire about the cultural competence of health care providers toward racial/ethnic minorities. Information on cultural practices and beliefs for the top six patient populations (African-American, Hispanic/Latino, Asian, Middle Easterner, Anglo-American, and South Asian) treated at Jacobi Medical Center was obtained from the PubMed database and anthropological textbooks. Using the following terms "cultural competency", "health care", "system", "racial/ethnic disparities" and "United States" combined, the search resulted in 44 articles. When applying the inclusion criteria such as journal articles published in English, free full text, and between 01/01/2003 to 9/31/2014, the search resulted in 15 journal articles. The information from these articles provides background knowledge related to cultural competency. In addition, information on cultural competence of interested racial/ethnic minority groups was gathered from anthropological textbooks (Rankin, Stallings 1996; Galanti 2004) and used to develop a one-hour PowerPoint presentation.

The PowerPoint presentation covered the following domains: defining cultural competency, barriers to cultural competency, model of care, model of disease and its etiology, cultural differences focusing on the population of interest, patient education, and strategies to work with patients in cross-cultural settings (Betancourt, Green, Carrillo, Ananeh-FirempongII 2003; Galanti 2004; Juckett 2005; Loftin, Hartin, Branson, Reyes 2013; Vaughn, Jacquez, Baker 2009). Handouts containing key topics addressed in the presentation were also developed for participants to take home (Rankin, Stallings 1996; Galanti 2004; See Appendix A). The

objectives of this presentation were that, upon completion of the presentation, learners will be able to: 1) improve cultural awareness, knowledge, and skills on treating racial/ethnic minority patients; 2) be more understandable, respectful, and tolerable to cultural differences; and 3) provide positive and meaningful interactions with patients and their families.

Based on the content covered in the PowerPoint presentation, a pre-post questionnaire was developed. Some questions for the survey were adapted from the Clinical Cultural Competency Questionnaire (Like 2001; http://www.rwjms.rutgers.edu/departments_institutes/family_medicine/chfod/grants_projects/documents/pretraining.pdf).

Results

The domains for the questionnaire were demographics, level of cultural competence, and self- graded attitude, skills, and knowledge toward socio-cultural issues as well as awareness of one's own identity, stereotype, prejudice, and bias. It was designed after the development of the slides for the PowerPoint presentation and was based on the contents of the presentation. Each questionnaire survey coded with an ID number, time, and date.

The questionnaire began with a purpose statement indicating that it was designed to assess participants' current experiences with cultural competency. It informed participants that their participation is voluntary and asked them to answer the questions to the best of their ability.

There were three sections in the questionnaire: Section I had five questions asking for demographic information including gender (male and female), age group (<25, 25-34, 35-44, 45-54, 55-64, >=65), self-identified race/ethnicity (White, Asian, African-American/Black,

Hispanic/Latino), country of origin (U.S., Puerto Rico, other U.S. territories), and years of experience in the health care system (<=5, 6-10, >10; see Appendix B).

Section II was used as the pre-questionnaire having six questions. Question 1 asked for the level of cultural competence (80-100%, 50-79%, or less than 50%) of the participants. Questions 2 through 6 were adapted from the Clinical Cultural Competence Questionnaire (Like 2001): Question 2 asked participants to grade their attitude or belief about the importance of socio-cultural issues in their interactions among patients, health professional peers, and staff. Question 3 asked participants about their feeling in dealing with cross-cultural encounters, such as caring for patients with diverse backgrounds and interpreting different cultural expressions of pain, distress and suffering. Question 4 asked participants to grade their knowledge about the socio-cultural characteristics, risk of disease, health disparities, different healing traditions, and experience of racism in health care among diverse racial/ethnic minority groups in the United States. Question 5 asked participants to grade their skill when dealing with socio-cultural issues in patient care, such as greeting patients, performing a physical examination, and providing patient education or counseling on a culturally sensitive manner, and eliciting patient's perspective about health and illness, folk remedies, and other healing modalities. Question 6 asked participants to grade their awareness of their own cultural identity, stereotype, bias, and prejudice. Questions 2 through 6 had five choices to respond using a Likert scale (0-4), including not at all (0), a little (1), somewhat (2), quite a bit (3), and very (4).

Participants were asked to complete Sections I and II of the questionnaire before attending the one-hour PowerPoint presentation on cultural competency. At the end of the presentation, participants were asked to complete section III.

Section III was used as the post-questionnaire with eight questions: Questions 1 through 6 were the same as in section II with the same way for the responses; question 7 and 8 were open-ended questions asking participants to identify some barriers to cultural competence at their work place and to comment on the strengths and weaknesses of the presentation.

The questionnaires were collected when participants leave the auditorium. A pre- and post-method of evaluation would be employed to address the pre- and post knowledge, skills, attitude, and awareness after the PowerPoint presentation. The information obtained in the pre-post questionnaires would be compared using the statistical software. The difference in the responses for questions 1 through 6 between section II and III would use to assess a measurable change in knowledge, skills, attitude, and awareness of cultural competence among nursing staff as a result of attending the presentation. A pilot testing of the questionnaire was conducted among 25 nurses at Jacobi Medical Center on May 1st 2014. All participants understood the questions and had no problem completing the questionnaire.

Conclusions/Discussion

The questionnaire was designed to assess the knowledge, skills, attitude, and awareness of nursing staff at Jacobi Medical Center with regards to cultural competency. This 19-question questionnaire had five domains that would be a valuable tool to determine the needs for additional educational training among nursing staff regarding cultural competency. This questionnaire could be an important instrument because it identified the weaknesses and strengths in cultural competence among nursing staff and targeted specific domain for cultural intervention.

When caring for diverse patient population, nursing staff need to educate about cultural competence by incorporating the slide presentation and the questionnaire into their educational training (Loftin, Hartin, Branson, Reyes 2013). Studies had shown that cultural competence training impacts nurses' and physicians' knowledge, attitudes, skills, and behaviors on treating racial/ethnic minority patients (Beach et al., 2005). In fact, ongoing cultural competence educational training and periodic assessment were recommended to ensure that nurses and physicians are up-to-date with cultural competence (Campinha-Bacote 2002).

A systemic review of nurses and physicians on cultural competence educational interventions by Beach et al. (2005) indicated that there is positive effect associated with whether the education on cultural competence is long or short duration, experiential or nonexperiential, and focusing on general or specific cultural information. The content of these cultural competence interventions focused on: 1) specific racial/ethnic minority groups' cultures (African-American, American Indian, Asian/Pacific Islander, Latino); 2) general cultural concepts (such as how culture impacts patient-doctor/nurse encounter; Tang et al. 2002); 3) how doctor/nurse's lack of knowledge of cultural norms and practices can adversely impact treating racial/ethnic minority patients (Rubenstein et al. 1992); 4) specific knowledge of traditional cultural practices regarding disease burdens on certain populations (Flavin 1997;Nora et al. 1994); and 5) attitudes toward treating health issues on the racial/ethnic community as well as showing interest in learning patient's background (Way et al. 2002). The methods of delivering these cultural competence interventions included lectures, group discussion, case scenarios, and audio/visual presentations, with contact time ranging from less than 8 hours to greater than one week. The overall outcome of these cultural competence interventions indicated a positive effect on nurses' and physicians' knowledge, skills, and attitude toward treating racial/ethnic patients

(Beach et al. 2005). Therefore, a one-hour PowerPoint presentation on cultural competence may assess the knowledge, skills, attitudes and awareness of nursing staff and may provide the foundation for a positive effect on nursing staff toward treating racial/ethnic minority patients.

The content of the pre-post questionnaire included questions about participants' level of cultural competence and participants' grading on their knowledge, skills, and attitude toward socio-cultural issues and cross-cultural encounters with patients, staff, and colleagues. It also asked participants to grade their awareness of their own cultural identity, stereotype, bias, and prejudice. Out of the 19 questions, ten questions were adapted from the Clinical Cultural Competency Questionnaire, which contains 56 validated and widely used questions (Like 2001). These questions were carefully selected to match with the content of the PowerPoint presentation.

There were strengths to the questionnaire and included: 1) the questions used in the survey were validated and reliable questions from the Clinical Cultural Competence Questionnaire (Like 2001); 2) the questionnaire was short containing 19 questions as compared to the 56 questions of the Clinical Cultural Competence Questionnaire (Like 2001). However, there were some limitations including: 1) because the questionnaire is self-reported, participants' responses may be bias; the questionnaire asks for participants' self-perception of cultural competence; nevertheless, participants might report what they considered as socially acceptable rather than as their perception (Capell et al. 2007; Kumas-Tan et al. 2007); and 2) this questionnaire was specifically designed to nurses in Jacobi Medical Center, a single NYC hospital, and therefore, it may not be used or generalized to other locations or all health care providers. However, nurses were the focus of this study because they represent the largest numbers (over 3 millions) of health care workforce, are first responder to encounter patients, and

are overrepresented (83.2%) by white/non-Hispanic (U.S. Department of Health and Human Services 2010). Jacobi Medical Center was chosen as the site for this study because it locates in northeast of the Bronx and its patients represent 90% of racial/ethnic minorities (Jacobi Medical Center 2013). This medical center has a national reputation in emergency medicine, trauma surgery, burn care, and neonatal care. In 2013, Jacobi Medical Center had 477 beds in service, 339,347 outpatient visits, 115,975 emergency room visits, and 21,669 discharges (Jacobi Medical Center 2014).

Recommendations

Although the development of the cultural competence training and the questionnaire are aimed to help increase nursing staff's knowledge, skills, attitude, and awareness toward treating racial/ethnic minority patients, there is additional works to be done to ensure achieving better health outcomes for minority patients and patients in general:

- To expand the use of the PowerPoint presentation and questionnaire not only to health care providers in general at Jacobi Medical Center but also to all NYC hospitals.
- To implement cultural competence training and assessment on nursing staff periodically to attain up-to-date cultural enrichment (Vaughn, Jacquez, Baker 2009).
- To mandate cultural competence not only to nurses but all health care staff as part of new hire orientation.
- To assess the level of cultural competence of hospital staff through patient satisfaction survey. Based on the patients' feedback, hospital administrators can determine whether having cultural competence staff will achieve better health outcomes for racial/ethnic minority patients or not. Hospital administrators can also use this feedback to reorganize their cultural competence

training and to learn and adopt specific cultural attitude to achieve more patients' satisfaction and better health outcomes.

Public Health and Policy Implications

As the U.S. population become more diverse, with the projection of minorities will comprise 57% of the U.S. population by 2060 (U.S. Census Bureau 2012), cultural competence training and periodic assessment for nursing staff are necessary to improve the health care services and health outcomes of racial/ethnic minority patient population. Studies have suggested that cultural competence training increases knowledge and skills of hospice staff, medical students, faculty and staff at Creighton University Medical Center in caring for racial/ethnic minority patients (Crosson et al. 2004; Schim, Doorenbos, Borse 2006; O'Brien et al. 2006). Other studies have suggested that patients who received cultural sensitive care from nurses and physicians report an increase in adherence to medical treatment plan and increase level of satisfaction with their nurses (Chenowethm et al. 2006; Cook, Omofolascade, Richard 2005). According to the national sample survey of registered nurses in 2010, there are over three million registered nurses, representing the largest portion of the U.S. health care workforce. However, the majority of these registered nurses (83.2%) are non-Hispanic whites and may be less likely to be cultural competent when treating racial/ethnic patients or minority patients may be less likely to develop a rapport and trust (U.S. Department of Health and Human Services 2010). Therefore, as the first responders and contact with racial/ethnic minority patients, registered nurses are the preferred group needing cultural competence training and assessment using the questionnaire as compared with other health care providers and staff.

Cultural competent trained nurses could improve population health by treating and serving racial/ethnic minority patients with cultural sensitive knowledge and skills; they can teach patients about disease, treatment options, and how to manage their medications, do exercises, change dressings, and participate in activities that promote independence and increase function. As a result of educating the patients, there will be an improvement in knowledge of disease and treatment plan, a better adherence to medical treatment, and a decrease in anxiety, symptoms, and readmission rates.

The questionnaire to assess cultural competence training can be implemented not only to nursing staff but also to other health care providers, health educators, and health administrators. By improving these healthcare stakeholders' knowledge and awareness toward cultural sensitivity of the growing racial/ethnic minority patient population, the attitude and culture of our health care system can be changed to accommodate the needs of minorities, such as interpreting service, and discussion of treatment plan and instructions for after care in their own language. This training can be integrated as part of hospital and/or CME education policy by requiring all personnel to attend an annual cultural competence training and assessment using the questionnaire. Attendees will gain enriched cultural development and will be equipped with cultural knowledge to better serve the diverse patient population and to achieve optimal health outcome.

The use of the PowerPoint presentation and questionnaire could be expanded to all New York City hospitals especially because the great racial/ethnic diversity New York City residents (U.S. Census Bureau 2010). Moreover, the PowerPoint presentation and questionnaire could be expanded to medical schools, nursing schools, and allied health schools because these institutions train and produce our health care providers. When everyone is knowledgeable about

others' cultural practices and beliefs, a better understanding, mutual respect, and satisfactory services can be accomplished in a diverse racial/ethnic community.

Appendix A

Do and Don'ts of Providing Culturally Competent Care

Do

1. Do remember to ask the right questions of all your patients: the *4 Cs* of culture
   - What do you *call* your problem?
   - What do you think *caused* it?
   - What have you done to *cope* with it?
   - What *concerns* you about it?
2. What *concerns* do you have about my recommended treatment?
3. Do try to understand people's values, since they will influence their behavior.
4. Do realize that not all patients believe germs caused their disease. Again, ask them what they think caused their illness.
5. Do recognize that people with a present time orientation may have difficulty with preventive health care. Make an extra effort to explain the importance of preventive health care, and why it is necessary to continue medication even after the symptoms have disappeared.
6. Do try to allow a patient as many visitors as she or he would like to have.
7. Do distinguish the degree of self-care necessary for recovery from that which is merely an imposition of the value of independence.
8. Do include family members in the patient teaching, if a family member will be caring for a patient at home.
9. Do respect a woman's concern for modesty; try to keep her covered.
10. Do try to assign same-sex health care providers when possible, especially for Middle Eastern patients.
11. Do be sensitive to the fact that most African Americans have been subjected to racial prejudice and discrimination.
12. Do respect patient's religious beliefs; involve clergy in their care when appropriate.
13. Do learn about the beliefs and practices of the patient populations you serve.
14. Do keep in mind that there is always individual variation within a group.
15. Do develop a tolerant accepting attitude about views different from your own.

Don'ts

1. Don't stereotype people.
2. Don't judge a patient's level of pain based upon their expressiveness. Some cultures encourage expressiveness, others encourage stoicism.
3. Don't wait to offer pain medication until a patient asks for it; many Asian patients will suffer in silence.
4. Don't assume lack of eye contact indicates lack of interest, or guilt, or some other negative point. For Asians, it may be a way of showing respect; for Middle Easterners, a way of maintaining propriety.
5. Don't judge people as "pushy" or "cold" based upon how close they stand to you.
6. Don't expect that all patients will make their own decisions. In cultures where the family is primary unit, important decisions may be made by the family. In cultures where males are dominant, the husband may make the final decisions regarding the health care of their wife and children.
7. Don't offer ice water as the only liquid for Asians and Hispanics. Many will prefer room temperature or warm liquids.
8. Don't confuse traditional health care practices such as coining and cupping with abuse.
9. Don't assume that a patient's appetite is based solely on feelings of hunger; some foods prepared by the hospital may violate rules of body balance or religious prohibitions, or may simply be unfamiliar to the patient.
10. Don't assume the patient wants to be informed of a fatal diagnosis. Ask the patient upon admission (or before, if possible) to whom he or she would like information about his or her condition to be given. Often family members will want to shield patients from a terminal diagnosis.

Questions to Ask During a Cultural Assessment

1. What do you think has caused your problem?
2. Why do you think it started when it did?
3. How severe is your illness? Will it have a long or short course?
4. What kind of treatment do you think you should receive?
5. What are the most important results you hope to get from this treatment?
6. What are the chief problems your illness has caused for you?
7. What do you fear most about your illness?

Source: Rankin, S.H., Stallings, K.D. Patient Education: Issues, Principles, Practices, 3rd Ed. Philadelphia: Lippincott Raven. 1996; 69

Characteristics of Cultural Embeddings

1. How recently did the patient immigrate?
2. Was the immigration voluntary or involuntary?
3. Did the patient live in intermediate countries before coming to the United States?
4. What country did the patient immigrate from and how different is that culture from U.S. culture?
5. Who does the patient associate with?
6. What type of neighborhood does the patient live in?
7. Does the patient follow traditional dietary habits?
8. Does the patient wear native dress?
9. Does the patient leave his neighborhood to participate in the larger culture?
10. Does the patient use folk medicine or see the practices of a native healer?
11. Does the patient come from an urban or rural area in the native country?

Appendix B

ID#_____ Time_____ Date_____

Pre-presentation Questionnaire Survey on Cultural Competency

The purpose of this survey is to assess your current experiences with cultural competency. Please answer the following questions to the best of your ability. Your participation in this study is voluntary. Your inputs are valuable to improve our program.

Section I

1) Which of the following age groups would you fit best?

A. <25 B. 25-34 C. 35-44 D. 45-54 E. 55-64 F. >=65

2) What is your gender? A. Male B. Female

3) Which of the following best describes you?

A. White B. Asian C. African American/Black D. Hispanic/Latino E. Other (specify): _____

4) Where were you born? A. U.S., Puerto Rico, or other U.S. territories B. Outside the U.S.

5) How many years of experience do you have with the health care system? A. <= 5 years B. 6-10 years C. More than 10 years

Section II

1) What would you say your level of cultural competence is? A. 80-100% B. 50-79% C. Less than 50%

2) How **IMPORTANT** do you believe socio-cultural issues are in your interactions with: (Please check one)*

	Not at all	A Little	Somewhat	Quite a Bit	Very
Patients?					
Health professional peers?					
Other staff?					

3) How **COMFORTABLE** do you feel in dealing with the following cross-cultural encounters or situations? (Please check one)*

	Not at all	A Little	Somewhat	Quite a Bit	Very
Caring for patients from culturally diverse backgrounds					
Being attentive to nonverbal cues or the use of culturally specific gestures that might have different meanings in different cultures					
Interpreting different cultural expressions of pain, distress, and suffering					
Advising a patient to change behaviors or practices related to cultural beliefs that impair one's health					

4) How **KNOWLEDGEABLE** are you about each of the following subject areas? (Please Check one)*

	Not at all	A Little	Somewhat	Quite a Bit	Very
Sociocultural characteristics of diverse racial and ethnic groups					
Risk of disease experienced by diverse racial and ethnic groups					
Health disparities experienced by diverse racial and ethnic groups					
Different Healing Traditions (e.g. Traditional Chinese Medicine)					
Historical and contemporary impact of racism, bias, prejudice and discrimination in health care experienced by various population groups in the United States					

5) How **SKILLED** are you in dealing with socio-cultural issues in the following areas of patient care? (Please check one)*

	Not at all	A Little	Somewhat	Quite a Bit	Very
Greeting patients in a culturally sensitive manner					
Eliciting the patient's perspective about health and illness (e.g., its etiology, name, treatment course, prognosis)					
Eliciting information about use of folk remedies and/or other alternative healing modalities					
Performing a culturally sensitive physical examination					
Providing culturally sensitive patient education and counseling					
Dealing with cross-cultural adherence/compliance problems					

6) How AWARE are you of your own: (Please check one)*

	Not at all	A Little	Somewhat	Quite a Bit	Very
Racial, ethnic, or cultural identity?					
Racial, ethnic, or cultural stereotypes?					
Biases and prejudices?					

Please do not proceed to section III until the presentation ends. Thank you!

Section III

Post-presentation Questionnaire Survey on Cultural Competency

1) What would you say your level of cultural competence is?
   A. 80-100%
   B. 50-79%
   C. Less than 50%

2) How **IMPORTANT** do you believe socio-cultural issues are in your interactions with: (Please check one)*

	Not at all	A Little	Somewhat	Quite a Bit	Very
Patients?					
Health professional peers?					
Other staff?					

3) How **COMFORTABLE** do you feel in dealing with the following cross-cultural encounters or situations? (Please check one)*

	Not at all	A Little	Somewhat	Quite a Bit	Very
Caring for patients from culturally diverse backgrounds					
Being attentive to nonverbal cues or the use of culturally specific gestures that might have different meanings in different cultures					
Interpreting different cultural expressions of pain, distress, and suffering					
Advising a patient to change behaviors or practices related to cultural beliefs that impair one's health					

4) How **KNOWLEDGEABLE** are you about each of the following subject areas? (Please Check one)*

	Not at all	A Little	Somewhat	Quite a Bit	Very
Sociocultural characteristics of diverse racial and ethnic groups					
Risk of disease experienced by diverse racial and ethnic groups					
Health disparities experienced by diverse racial and ethnic groups					
Different Healing Traditions (e.g. Traditional Chinese Medicine)					
Historical and contemporary impact of racism, bias, prejudice and discrimination in health care experienced by various population groups in the United States					

5) How **SKILLED** are you in dealing with socio-cultural issues in the following areas of patient care? (Please check one)*

	Not at all	A Little	Somewhat	Quite a Bit	Very
Greeting patients in a culturally sensitive manner					
Eliciting the patient's perspective about health and illness (e.g., its etiology, name, treatment course, prognosis)					
Eliciting information about use of folk remedies and/or other alternative healing modalities					
Performing a culturally sensitive physical examination					
Providing culturally sensitive patient education and counseling					
Dealing with cross-cultural adherence/compliance problems					

6) How **AWARE** are you of your own: (Please check one)*

	Not at all	A Little	Somewhat	Quite a Bit	Very
Racial, ethnic, or cultural identity?					
Racial, ethnic, or cultural stereotypes?					
Biases and prejudices?					

7) Can you identify some barriers to providing culturally competent care in your work place?

_____

_____

8) Please offer any comments with regard to the strengths and weaknesses of this presentation on addressing the topic.

a. Succinct synthesis of results	x					
b. Interpretation of results in context of literature		x				
c. Summary of strengths and limitations of project	x					
d. Recommendations based on study or project findings and a conclusion/take home message	x					Well done
7. Organized paper logically and in accordance with instructions, including:						
a. Correct length (3000-5000 words) and format (subheadings, margins, spacing)	x					
b. At least a minimum of 15 references, including ≥6 peer-reviewed sources	x					
c. Complete references, using AJPH format	x					
d. Proper attribution for all facts	x					
e. Correct spelling and grammar	x					
8. Organized paper in a clear and effective **style,** including:						
a. Ideas within & between paragraphs laid out in a clear & logical fashion	x					
b. Clear paper flow; readable		x				
c. Appropriate language for scientific writing		x				

Action to be taken, please check one:

x This paper is acceptable with no revisions.

Please comment on your reason for selecting the above choice:

Well done paper. No significant content revisions required. The paper focused on Tdap in pregnancy as a prevention method for protecting infants from pertussis before they are fully vaccinated. Because it was such a small body of literature, I would have recommended more comparison to the cocoon method and to include more data on pregnant women's acceptability of vaccination during pregnancy. However, for the defined project, it was well completed. I appreciated the international context being included.

Maternal Tdap Vaccination During Pregnancy as a Method of Protection Against Infant Pertussis: A Systematic Literature Review

Capstone Faculty: Karyn Faber, EdD, MPH

May 16, 2015

Abstract Word Count: 243

Text Word Count: 4,214

Abstract

Objectives

In 2012, the Advisory Committee on Immunization Practices (ACIP) recommended a Tdap vaccine booster during pregnancy as an effort to protect infants against pertussis. This systematic review seeks to address the effects of Tdap during pregnancy on both mother and child, assess whether there are any safety concerns associated with this practice, and evaluate trends in vaccine uptake to determine whether any challenges or barriers exist in the implementation of ACIP Tdap vaccination guidelines.

Methodology

Guided by PRISMA standards, a search was conducted using the online databases MEDLINE, ProQuest, PubMed, Science Direct, and the New York Academy of Medicine's grey literature collection. Peer-reviewed journal articles published between 2004 and 2015 were selected for review if they pertained to pregnancy dose Tdap vaccination as a source of protection for infants against pertussis.

Results

Fifteen articles were selected for review. Eight studies investigated the effects of receiving Tdap during pregnancy. Three studies completed assessments on the safety of receiving Tdap during pregnancy. Four studies investigated the trends in Tdap vaccine acceptance among pregnant women.

Conclusions

Evidence presented in this systematic literature review appears to support the ACIP's Tdap recommendation for pregnant women as a safe and effective method of providing protection against pertussis for infants too young to receive vaccination. Efforts to implement these guidelines should target health care professionals as sources of information for pregnant women. Future studies should investigate disparities in Tdap acceptance to determine whether cultural, geographical, or socioeconomic barriers exist.

I. Introduction

Despite the widespread availability of vaccines and more than 60 years without a significant outbreak, pertussis- or "whooping cough"- has reemerged as a threat in the United States. Recent years have produced significant increases in pertussis cases, reaching status as epidemic in California in 2010 and again in 2014.[1] Though pertussis outbreaks tend to be cyclical, these increases have required public health officials to take action to reduce the burden of this disease, particularly for those who are unable to receive protection in the form of vaccinations.[2]

A. Epidemiology

Pertussis, caused by the bacterium *Bordetella pertussis,* is a contagious respiratory infection which may be transmitted from one person to another via coughing or sneezing in close contact.[3] It occurs in three stages: the catarrhal stage, the paroxysmal cough stage, and convalescence.[2] Within the first two weeks (the catarrhal stage) of pertussis, the infected individual displays runny nose, sneezing, a low fever, and an occasional cough which worsens as pertussis moves into the second stage for approximately one to six weeks.[2] In this paroxysmal cough stage, the individual experiences bursts of coughs which are followed by a high-pitched "whoop" caused by efforts to catch ones breath.[2] These episodes may lead to vomiting and exhaustion.[2] Recovery from infection and gradual decrease in coughing occurs in the convalescence stage, though this may take weeks or months depending on severity.[2]

Although rare, pertussis may be deadly due to severe complications in the form of pneumonia, seizures, or encephalopathy.[2] The introduction of pertussis vaccinations led to a gradual decrease in pertussis incidence, from approximately 175,000 cases per year in the early

1940's to less than 3,000 cases per year in the 1980's.[2] Since the 1980's, however, pertussis case numbers have continuously risen to the epidemic levels seen today.[2]

B. History of Pertussis in the United States

Surveillance efforts for pertussis cases began in 1922, in which 107,473 cases were reported in the United States.[4] Reported cases grew to an all-time high of 265,269 cases in 1934 before decreasing significantly as the first pertussis vaccine was introduced in the 1940's.[4] Following this introduction of the pertussis vaccine known as DTP (diphtheria, tetanus, and pertussis), pertussis cases declined significantly to rates below 10,000 cases per year by 1965.[4] These low rates continued until 2003 when reported cases rose to 11,651, followed by continual increases reaching approximately 48,277 pertussis cases in 2012.[4] Pertussis events tend to be cyclical, peaking every two-to-five years (explanations for the cyclic nature of pertussis were not found),[5] though recent numbers have been significant for pertussis cases in the United States. Theories on the recent surges in pertussis cases are varied and include decreases in vaccination rates as well as speculated decreases in vaccine effectiveness.[1,2,5]

In 2010, California made headlines when pertussis cases warranted the label of epidemic with more than 9,000 cases, 809 hospitalizations, and 10 deaths.[6] Washington experienced its own epidemic two years later with a 1,300% increase in pertussis cases in 2012.[7] Nationally, the year 2012 produced the highest number of pertussis cases since the 1950's with 48,277 cases reported to the CDC.[4] This number more than doubled the cases reported in the previous year. Although pertussis cases have since decreased, pertussis has remained a concern as California reported another epidemic in 2014.[1] To date, there have been no studies to uncover a single cause for the recent rise in pertussis cases. Unvaccinated individuals and those who have not completed

the full course of pertussis vaccinations are at the highest risk for disease and pertussis-related death.[6]

1. Development of Vaccines for Pertussis Prevention

In the late 1990's, the Food and Drug Administration licensed an acellular pertussis vaccine known as the Diptheria, Tetanus, and acellular Pertussis (DTaP) vaccine, after the previously developed whole cell pertussis vaccine of the 1930's (known as DTP) caused concerns over safety and effectiveness in the United States.[2] The Advisory Committee on Immunization Practices recommends that the DTaP vaccine be administered to children at ages 2 months, 4 months, 6 months, between 15 and 18 months, and at 4 to 6 years.[8] In 2005, another vaccine known as the Tetanus, Diptheria, and acellular Pertussis (Tdap) vaccine was licensed for use in adolescents and adults.[2] This vaccine is administered as a booster dose between ages 11 and 18 years and can be received every 10 years to maintain protection.[2]

Although the DTaP and Tdap vaccines have significantly reduced the burden of pertussis in the United States, infants under the age of 3 months remain at high risk for pertussis infection and pertussis-related deaths because they have not yet been fully vaccinated against the disease.[6] Between 2004 and 2008, 83% of deaths from pertussis infection in the U.S. were attributed to infant aged three months or younger.[2] Because of the two-month waiting period for the DTaP vaccine, public health professionals have been tasked with creating solutions which would protect this at-risk population.

C. Immunization Practices to Protect Infants

A retrospective study of the 2010 California pertussis epidemic concluded that unrecognized pertussis in adolescent and adult contacts of infants was a significant source of pertussis in infants less than 6 months old, as most subjects were noted to have a household

contact with a cough at the time of infection.[9] Similar research has shown that parents and grandparents, as well as siblings to a varying degree, are significant sources of pertussis in infant cases.[10] In 2005, the Advisory Committee on Immunization Practices (ACIP) began recommendations for the use of the "cocoon method" as a protective measure against infant pertussis.[2] This method recommends that all close contacts of infants are advised to receive the Tdap booster vaccine at least two weeks prior to contact with the infant in an effort to shield the infant from pertussis infection.[11] Despite recommendations and an increase in adult vaccination coverage in the United States,[12] pertussis-related infant mortality has remained a significant problem warranting further efforts in protecting this at-risk population.

1. Maternal Tdap during Pregnancy

In 2012, the ACIP recommended the Tdap vaccine during every pregnancy as a protective measure for infants.[13] In 2013, the ACIP added to this recommendation, indicating that immunization should take place between weeks 27 and 36 of pregnancy.[13] As of this date, no recent systematic literature reviews have addressed the usage of the Tdap vaccine during pregnancy as a protective measure for infants. As this is a newly recommended strategy, there is a need for a systematic review to present and evaluate current research on this pertussis prevention strategy. This systematic literature review seeks to address the following research questions:

1. Are there any effects of receiving Tdap during pregnancy for both mother and infant?
2. Are there any reports assessing safety or adverse events associated with receiving Tdap during pregnancy?

3. Do any challenges or barriers exist in the implementation of the ACIP vaccination guidelines, including trends in Tdap acceptance and attitudes toward vaccinating during pregnancy?

Upon a complete analysis of the evidence presented, further steps to implement this strategy or create a new strategy may be taken by public health professionals.

II. Methods

The goal of this review is to investigate the effect, safety, and barriers, if any, to administering Tdap to women during pregnancy as a protective strategy against infant pertussis. Previous systematic reviews have assessed the use of the cocoon method of protection against pertussis, yet none have specifically reviewed Tdap vaccination in pregnancy. For this reason, and because this method is no longer the preferred protective strategy, articles that focused strictly on the cocoon method were not included in this review. The search strategy and analysis for this review was guided by the PRISMA Statement for Reporting Systematic Reviews.[14] The PRISMA Statement is a guide to developing systematic review methodologies and includes a checklist of items to include when reviewing articles.[14] The PRISMA Statement was selected for this review because it provided a framework to ensure that every article chosen for review met the necessary criteria and was fully analyzed in this report.

A. Search Strategy

Table 1 illustrates the search strategy utilized to collect articles for this review. Three search strategies were employed to attempt to account for the possibility for scarce and diverse publications. First, the online databases MEDLINE, ProQuest, PubMed, and ScienceDirect were searched for studies published in peer-reviewed journals. All study designs were considered for review due to the broad nature of the initial research question. As some searches yielded few

results, including all designs provided better odds that articles could be found through a search of article reference lists. Second, a separate search using the search strategy outlined in Table 1 was conducted using the New York Academy of Medicine's grey literature collection. Finally, additional articles were identified by searching reference lists of relevant studies.

B. Study Selection

Studies were included if the subject of their investigation pertained to pregnant women receiving the Tdap vaccine and/or the resulting health effects on their infants (under 12 months of age). Additional inclusion criteria included a publish date between January 2004 and February 2015 in a peer-reviewed journal. These dates were selected to coincide with the introduction of the Tdap vaccine. Studies were excluded if maternal Tdap was only administered to participants postpartum or if the focus of the article pertained to the cocoon strategy of pertussis prevention. Non-English studies were excluded, though non-US studies were considered for review. Literature reviews were excluded from analysis but considered for background information to establish rationale for a systematic review.

C. Quality Assessment

Studies selected for further review were organized under three categories: Effect of Maternal Tdap during Pregnancy on Infant Pertussis; Safety of Receiving Tdap Vaccine during Pregnancy; and Implementation of Recommended Vaccination Practices for Pregnant Women. These studies were reviewed and organized into data tables according to subject categories (see Tables 2, 3, and 4). Data tables were used to specify study design, sample, objectives, results, findings, and conclusions for all articles. Further exclusions of articles were made based on suspected bias or lack of relevant data (see Figure 1).

III. Results

The initial database search generated 195 articles, of which 52 were excluded because they were duplicates. Figure 1 illustrates further exclusion procedures in which 108 articles were excluded based on a review of article titles and abstracts. The majority of these articles were excluded because they did not pertain to maternal Tdap vaccinations (n=55). Other articles were excluded based on participant characteristics (i.e. non-pregnant women or infants over 1 year of age, n=30), an emphasis on the cocoon strategy (n=13), or non-English language (n=10). Upon a full-text review of 35 articles, 20 articles were further excluded based on reasons previously noted. Ultimately, 15 articles were selected for this review.

A. Study Identification

Articles selected for review were separated into 3 categories according to study objectives and subject matter: 1) Effects of Receiving Tdap during Pregnancy; 2) Assessments of Safety of Tdap during Pregnancy; and 3) Implementation of Tdap Vaccination Guidelines. Tables 2, 3, and 4 summarize study design, sample, objectives, results, findings, and conclusions of the articles within each category. Overlap among subject categories was common. Participants were women who were either pregnant at the time of investigation or who had given birth within a timeframe selected by the investigators. For case control studies, women who received Tdap during pregnancy represented case groups while women who were not documented as receiving Tdap during pregnancy represented the controls.[15, 16, 17, 18, 19, 20]

1. Effects of Receiving Tdap during Pregnancy

Eight of the studies selected for review investigated the effects of receiving Tdap during pregnancy; either in an attempt to explain how infants may be protected through this methodology or to compare Tdap during pregnancy with postpartum vaccination or the cocoon methodology (see Table 2). Five observational studies used maternal and infant blood samples to

measure the impact of maternal Tdap vaccination in pregnancy.[16, 17,21, 22, 23] Breast milk samples were used to determine pertussis-specific antibody levels in one study.[15] The remaining two studies used published data for their analyses on the effects of Tdap vaccination.[20,24]

a. Effects of Maternal Tdap on Newborn Pertussis Antibody Levels

Immunoglobulin G (IgG) is a type antibody that is responsible for defense against bacterial attacks and is transferred via placenta from mother to child.[25] Geometric Mean Concentrations (GMC) of IgG to pertussis toxins are used in studies to measure levels of protection against pertussis. Ercan et al.[22] examined the presence of anti-pertussis antibodies in term and preterm maternal and newborn cord blood samples to evaluate the process of mother-to-infant antibody transfer. Participants in this study were not vaccinated with Tdap.[22] This transplacental antibody transfer may explain the need for maternal Tdap vaccinations during pregnancy. Using an observational design, Ercan et al.[22] found that anti-pertussis antibody levels are naturally low in maternal-infant pairs, especially so for preterm pairs. In another study, transplacental transfer of pertussis antibodies was observed in pregnant women who received a Tdap booster vaccine at or past 20 weeks gestation and their newborns.[23] Prior to Tdap vaccination, significant anti-pertussis toxin (PT) levels were found in 37.1% of maternal samples whereas 90.2% of post-vaccination maternal samples indicated significant ($\geq$10 IU/ml) anti-PT levels.[23] Transplacental transfer ratio for anti-PT antibodies was 146.6% and at 2 months, 66% of participating newborns had significant anti-PT levels.[23]

A similar study was conducted to compare anti-PT antibodies in newborns of mothers who received Tdap to newborns of mothers who did not receive Tdap.[16] Based on concentrations of anti-pertussis antibodies in maternal and umbilical cord blood, Gall et al.[16] found a statistically significant increase in the odds that newborns of mothers who receive Tdap during pregnancy

will have protective antibodies against pertussis toxin compared to newborns of unvaccinated mothers.

Abu Raya et al.[15] investigated lactation as a method of antibody transfer from mother to infant. Breast milk of women who were vaccinated after the 20th week of pregnancy provided a greater GMC of pertussis-specific antibodies than that of women who were not vaccinated.[15] The most significant differences among the two groups were seen in the colostrum during late pregnancy, but detectable antibody levels remained in the vaccinated group throughout the 8-week postpartum period of study.[15] Significant decline in antibody levels were observed over 8 weeks in both groups.

To assess whether maternal Tdap affects infant response to DTaP immunization, Hardy-Fairbanks et al.[17] observed infant blood samples at birth, before DTaP immunization, and after DTaP immunization. At the time of birth, maternal and cord blood samples of the Tdap group had higher concentrations of anti-PT antibodies compared to the unvaccinated group.[17] These higher concentrations continued to be evident at the time of the 2 month mark in which DTaP was administered to the infants, however a lower concentration of antibodies was observed in the Tdap group after DTaP was given to the infants.[17] Differences between the Tdap group and the non-Tdap group were not evident at time of the 18 month booster DTaP vaccination.[17]

Using published data on infant pertussis hospitalizations in conjunction with literature on vaccine effectiveness, Peters et al.[24] estimated the impact of parental Tdap vaccination on infant pertussis hospitalizations. Overall findings indicated maternal vaccination (without paternal vaccination) at least 2 weeks prior to delivery could prevent between 1,347 and 6,909 hospitalizations of infants between 0 and 5 months of age.[24] Maternal vaccination at the time of

birth hospitalization and at 2 weeks postpartum was estimated to prevent between 1,093 and 6,139 hospitalizations and between 839 and 5,369 hospitalizations, respectively.[24] A similar analysis was conducted by Terranella et al.[20] using a cohort of U.S. births in 2009 estimate the impact of pregnancy dose Tdap on infant pertussis incidence, hospitalizations, and deaths. Based on this analysis, Terranella et al.[20] concluded that Tdap during pregnancy could reduce infant pertussis cases by approximately 33%, hospitalizations by 38%, and deaths by 49%. In a comparison to postpartum vaccinations, Tdap during pregnancy was found to be a more effective and more cost efficient option for reducing the burden of infant pertussis.[20]

b. Variation in Effect Based on Timing of Vaccination

One study observed the impact of timing on the effects of receiving Tdap during pregnancy using a prospective design.[21] Using Geometric Mean Concentrations (GMC) of IgG in newborn cord blood to measure protective power, Abu Raya et al.[21] measured the impact of vaccination in during weeks 27 to 30, weeks 31 to 36, and after the 36th week of pregnancy. The highest rate of anti-pertussis antibody transfer was seen between weeks 27 and 30 of pregnancy, indicating the highest odds for pertussis protection for infants.[21]

Based on a review of these eight studies, it is evident that the effects of maternal Tdap vaccination can be found in both cord blood and breast milk; however, effects are shown to be strongest within blood samples. [15, 16, 17, 22, 23, 24] Only one study looked at lactation as a method of transfer for anti-pertussis antibodies, which leaves room for further research to determine the effects of breastfeeding after receiving Tdap in pregnancy. Despite ACIP recommendations for vaccination between weeks 27 and 36 of pregnancy, a more accurate timeline for vaccination would be between weeks 27 and 30 of pregnancy.[21]

2. Assessments of Safety of Tdap during Pregnancy

Three articles sought to determine whether Tdap vaccination during pregnancy is safe for pregnant women as well as infants (see Table 3). To assess safety, reports of vaccine adverse events were reviewed and characterized according to whether or not Tdap was administered during pregnancy.[18,26] In one study, Tdap during pregnancy was associated with a small but statistically significant increase in risk of chorioamnionitis (bacterial infection of the fetal membranes).[18] Within this same study, no association was found between Tdap vaccination during pregnancy and increased risk of preterm delivery, SGA (Small for Gestational Age) birth, or fetal hypertensive disorders.[18] A retrospective cohort study involving mothers aged 12 to 45 who either received Tdap during pregnancy or had no documented Tdap vaccination found no significant difference in preterm delivery, gestational age, or birth weight of infant between both participant groups.[19]

All 3 studies concluded with statements to indicate that Tdap during pregnancy is as safe for mother and infant as not receiving the vaccine at all or opting to receive the Tdap vaccine after giving birth. A potential concern regarding the studies selected for safety assessments is a small sample size of pregnant women who received Tdap during pregnancy. One study attributed just 21% of the study sample (n=123,494) to women who received Tdap during pregnancy[18] while another attributed 20% of their sample size (n=690) to women who received Tdap during pregnancy.[19]

3. Implementation of Tdap Vaccination Guidelines

In addition to reviews of safety, four studies were selected for an assessment of general trends in Tdap vaccination and attitudes toward receiving the vaccine while pregnant (see Table 4). Kharbanda et al.[27] observed medical record and claims data from seven sites across the

United States (Northern California, Southern California, Colorado, Minnesota, Oregon, Washington, and Wisconsin) to assess Tdap vaccine uptake during pregnancy. Coinciding with recommendations from the California Department of Public Health for Tdap during pregnancy, the percentage of women in California who received Tdap during pregnancy increased between 2007 and 2011, from 0.3% vaccinated to 30% vaccinated, but this rate dropped to 19.5% in 2012.[27] Across all other sites included in this study, Tdap uptake during pregnancy rose from 0.8% in 2007 to 16% in 2012.[27]

In a retrospective cohort study, three factors were shown to be independent predictors for whether or not pregnant women would opt to receive the Tdap vaccine: 1) Black women were less likely to receive the Tdap vaccine; 2) Women who delivered preterm were less likely to receive the Tdap vaccine; and 3) Women were more likely to accept the Tdap vaccine during pregnancy if they had also received the influenza vaccine during pregnancy.[28] Racial disparities in vaccine acceptance were speculated to be a result of differing attitudes toward vaccination, however further research on this topic is required.[28] Lower rates of vaccination among women who delivered pre-term may be explained by the general trend of receiving the vaccine in the later stages of pregnancy.[28] The most frequently reported reason for vaccine refusal was concern for maternal and infant safety.[29]

The ACIP is a United States entity, however guidelines for Tdap during pregnancy have been implemented internationally.[29,30] In a cross-sectional survey of 402 pregnant women in Mexico City receiving prenatal care in three designated public healthcare centers, 16% of respondents reported some knowledge of pertussis and 57% indicated intent to receive the Tdap vaccine if offered.[29] More than 80% of survey respondents indicated that they would accept the vaccine if it was recommended by an obstetrician-gynecologist.[29] Similar findings were

produced in a cross-sectional survey of Australian women by Wiley et al.,[30] who found that women receiving a professional recommendation for Tdap were seven times more likely to accept Tdap vaccination. All four studies selected to assess challenges or barriers to implementing ACIP guidelines found that recommendations from health care professionals increased the odds that pregnant women would choose to receive the Tdap vaccine during pregnancy.[27,28,29,30]

IV. Discussion

The aims of this systematic literature review were to investigate the effects of receiving Tdap vaccination during pregnancy as a protective measure against infant pertussis, review reports on the safety of receiving Tdap vaccination during pregnancy for mother and child, and assess current trends in and attitudes toward Tdap vaccination among pregnant women as an indicator for the implementation of vaccination guidelines. Based on research which included meta-analyses as well as observational cohort studies, newborns of women who received the Tdap booster during pregnancy had the highest odds of protection against pertussis infection compared to newborns of women who received Tdap postpartum or did not receive the Tdap booster at all.[15, 16, 17, 20, 21, 22, 23, 24] This protection is a result of anti-pertussis antibody transfer from mother to child via breast milk[15] and the placenta.[16, 17, 21,22, 23] Although the evidence supporting antibody transfer via breast milk was significant, only one study explored this method of mother-to-child protection. Antibody transfer via lactation is an area that should be further examined to determine if there is an added protective benefit in breastfeeding.

As with any medical procedure, it was necessary to review all available evidence pertaining to the safety of this vaccination strategy. Based on the results of two cohort studies and one clinical review, Tdap during pregnancy was generally accepted as a safe procedure.[18, 19,

[26] One study did find a small but statistically significant increase in risk for chorioamnionitis, but no association was found with other conditions such as hypertensive disorder or preterm birth.[18] Assessing the safety of this protective strategy is essential when considering future directions for prenatal health care.

To assess the implementation of the ACIP guidelines for Tdap during pregnancy, this review included four articles on the topic of vaccination trends and attitudes toward vaccination during pregnancy among pregnant women.[27, 28, 29, 30] A common conclusion among these articles indicates that women are more likely to choose to receive the Tdap booster if it is recommended by a health care professional. [27, 28, 29, 30] One issue that surfaced in reviewing these articles was apprehension in receiving Tdap among pregnant women based on a lack of knowledge of pertussis and the Tdap vaccine or a fear of harming their unborn child.[29, 30] Black women were found to be less likely to receive Tdap during pregnancy, however no explanation was provided.[28] There remains a need to research this finding to determine whether there are any barriers to receiving the Tdap vaccine. Future implementation efforts should take into consideration these potential barriers and factors of vaccine refusal in order to effectively increase Tdap vaccination among pregnant women and ultimately reduce the prevalence of pertussis among infants.

V. Limitations

As the research on the effects of maternal Tdap during pregnancy is somewhat recent, this systematic review was limited by the availability of studies that fit the designated criteria. In the process of article collection, many studies appeared to have a greater emphasis on postpartum vaccinations as well as the cocoon strategy for pertussis protection. Sample size presented another limitation as many of the studies investigated relatively small proportions of women who

received the Tdap vaccine during pregnancy. Although findings were significant, these conclusions may have been strengthened by a larger proportion of women who received Tdap during pregnancy. Safety assessments may have been further strengthened by larger sample sizes.

VI. Conclusion

The Advisory Committee on Immunization Practices began recommending the Tdap vaccine booster in pregnancy in 2012.[2] Despite the relatively recent nature of this recommendation, and therefore limited selection of research studies, evidence presented here appears to support the ACIP's guidelines for pregnant women. Tdap vaccination during pregnancy has been shown to be a safe[18, 19, 26] and effective method[15, 16, 17, 20, 21, 22, 23, 24] of providing pertussis protection to infants until they are old enough to receive DTaP vaccination at 2 months old. Efforts to implement the ACIP guidelines for Tdap during pregnancy should target health care professionals as informational sources for pregnant women. Future research efforts should seek to include a larger sample of pregnant women who receive Tdap during pregnancy. Additionally, future research should investigate disparities in Tdap usage to determine whether cultural, geographical, or socioeconomic barriers exist.

b. At least a minimum of 15 references, including ≥6 peer-reviewed sources	x					
c. Complete references, using AJPH format	x					

	C	S	P	N	N/A	Comments on Quality
d. Proper attribution for all facts	x					
e. Correct spelling and grammar	x					
8. Organized paper in a clear and effective **style,** including:						
a. Ideas within & between paragraphs laid out in a clear & logical fashion	x					
b. Clear paper flow; readable	x					
c. Appropriate language for scientific writing	x					

Action to be taken, please check one:

___This paper is acceptable with no revisions.

___This paper should be acceptable once the author makes the indicated revisions.

___This paper should be acceptable once the author makes the major revisions indicated

___This paper is unacceptable.

Please comment on your reason for selecting the above choice:

This is a strong and well written paper. Whether it is acceptable with revisions or acceptable as is I will leave to Prof. Faber.

P2. And p. 10. When describing objectives be more explicit (esp in abstract). Your objective was to compare bike share *trip characteristics* between rides taken by full pay members and rides taken by discount members who were targeted in low income communities. Through examination of utilization data, you hoped to make inferences about the success of the equity program and develop ideas for further testing. (or something like that)

p. 12. In describing you data cleaning procedures, your use of terminology is not quite right. I think you mean to say that you recoded text variables (those where the data was comprised of words) to either dichotomous variables (two levels, usually coded 0 1 and often "oppostite" or to categorical variables (multiple categories that are not implicitly better/worse, higher/lower, etc.). you recoded age into an ordinal variable (unequal categories that have order).

p. 15. Includes an example of language-around-sampling-unit problem. You say, "Among women in particular, discounted members appear to be older than general members." But really all you can say is that

a greater proportion of the discounted rides was taken by older women, compared to the full-pay rides. Use caution throughout with respect to how you articulate findings that are based on *rides*, not riders. You do not know to what extent your data are driven by repeat users.

Seasonality

Bike trip data likely have seasonality. If we suspect that membership type is driven by race and economics, how might patterns of summer time use of bikes differ by race and economics.

Conclusions

These data suggest that equity programs can be successful and that rides taken by discounted members do not look that different from rides taken by full pay members. However, since trip is unit of analysis, can you conclude that program successfully overcame barriers to ridership? Do you have any user data that could speak to that question?

Tables

Tables should not be SPSS output.

Many tables (4,5,6 and 7) should be oriented in the opposite direction. In other words, since you are comparing general to discounted rides (not "member") that data should be in your column, so reader can easily compare. For example, look how hard it is to compare the 29.9% and the 51.1% in Table 6. Those are the numbers you want to highlight, not hide. And the eye likes to compare *across*, not up and down. Keeping type of ride in the columns will also avoid having to repeat so much text as in Table 4 which completely replicates the table (mean, median, st. dev., etc.). Same for Table 5, in which you don't even need the "outside commute time" data. The title is Trips Taken During Weekday Commute, so just show that data.

Overall, great job. I know these data fell short of what you wanted and I'm sure they were difficult to work with. Your background is one of the best I've read. And you do find a "gap."

FINAL

Bike share and equity in New York City: Research on the utilization of the Citi Bike discounted membership program

Graduate Student
Hunter School of Public Health, Community Health Education Program

Submitted to Dr. Karyn Faber
May 16, 2015

ABSTRACT

Background
Public bike sharing systems can facilitate active transportation by increasing population access to bicycles, thereby increasing population levels of physical activity. But, bike sharing systems across the country struggle to reach those who could benefit from them most. In response, many systems have developed equity initiatives. By examining trip-level data, we assessed one such initiative in New York City, and developed recommendations for system administrators.
Methods
We obtained three months of complete Citi Bike utilization data and compared discounted members to general (full-price) members. We examined personal characteristics (gender and age), and trip characteristics (trip duration, trip start day and time, and trip start location).
Results
Citi Bike members took 2,494,553 trips from June 1, 2014 through August 31, 2104. Discounted members accounted for .6% of all trips (15,427). Men under age 45 took the majority of all trips, but a higher proportion of trips were taken by women and those ages 45+ among discounted members. Discounted members' trips had similar characteristics to general members' trips.
Conclusion
Citi Bike's discounted membership program is more gender equitable than general cycling in New York City, and suggests a demand for active transportation options for low-income older women. Discounted members' use of the Citi Bike system suggests that some low-income New Yorkers have integrated bike sharing into their travel habits. A better understanding of the initiative's target population and a plan for program growth based on repeated data analysis are recommended.

INTRODUCTION

The health benefits of physical activity are well-established.[1] Active transportation – biking and walking to destinations – can increase physical activity, and has been associated with better fitness, reduced risk for cardiovascular disease, and lower rates of obesity and diabetes.[1,2,3] In a nation where nearly 63% of adults are overweight or obese, more than 80% of adults do not meet physical activity guidelines, and only 1% of all trips are taken by bicycle, initiatives to increase bicycling, particularly bicycling for transportation, are now a major public health aim. [4,5,6,7] *Healthy People 2020* targeted a 100% increase in the proportion of trips under five miles American adults make by bicycle, emphasizing the potential of active transportation. [8]

A national survey of over 16,000 adults found that nearly half of Americans age 18 and older (48%) do not own an operational bicycle, though 54% reported that bicycling is convenient and 53% would like to ride more often.[9] By increasing population access to bicycles, public bike sharing programs have the capacity to help reach the *Health People 2020* benchmark, contributing to population levels of cycling and, as a result, increasing population levels of physical activity.[10,11] However, bike sharing systems across the country have been criticized for failing to reach women, low-income individuals, and people of color, despite their efforts to do so.[12] This study, the first of its kind, evaluated one such effort in New York City, describing the characteristics of low-income residents who joined and used the city's bike sharing system, and the characteristics of their bicycle trips over the course of three months in 2014. The findings from this study may be useful to academics, health professionals, and bike share system operators, who, until now, have had

Commented [EC1]: Removed "alike"

little or no information on which low-income individuals incorporate bike sharing into their lives and how they do so.

Background

Public bike sharing systems make bicycles available for short-term rentals from a network of self-service stations, typically located throughout a city center. Considered a relatively easy and affordable way to enhance existing transit infrastructure, bike sharing claims many benefits beyond increasing physical activity, from reducing carbon emissions, noise pollution, and traffic congestion to improving mental health.[7] Since the country's first Information-Technology-based system launched in Tulsa, Oklahoma, in 2007, the number and size of bike sharing systems in the United States has grown rapidly.[13] In 2014, 34 systems were operating in the U.S., with new programs debuting annually.[14]

New York City's bike sharing system, the largest in North America, launched in May 2013 with 6,000 bicycles at over 330 stations in Manhattan and Brooklyn. An initiative of the NYC Department of Transportation, Citi Bike is privately funded through corporate sponsorships and does not rely on any public funding. NYC Bike Share, a private company, handles day-to-day operations of the system, including sales, marketing, and promotion. Citi Bike access is available through the online purchase of an annual membership or through the purchase of a 24-hour or 7-day casual pass at any station kiosk. Nearly two years after launching, the system has sold over 120,000 annual memberships and hundreds of thousands more casual passes; users have taken a total of 16 million trips and traveled an estimated 30 million miles.[15]

One study of Barcelona's bike sharing system, Bici, found that the Bicing initiative increased cycling trips in that city by 30% between 2007 and 2011.[16] Bike share system

operators and city officials seeking to implement new systems are often interested in highlighting this impact and promoting the health benefits gained through their members' activity.[13] In New York City, Citi Bike assessed its users burned 50 million calories in just the first month of operation (assuming a calorie burn rate of 40 calories per mile biked).[13] Similar systems tout more specific health benefits: a 2012 survey of Capital Bikeshare users in Washington, D.C., found that of over 3,100 responses, 31.5% reported reduced stress, and about 30% indicated they lost weight due to using Capital Bikeshare.[13]

Equity Concerns

Across the country, though, bike sharing systems struggle to achieve *equity*, defined in part by the National Academy of Public Administration as "the fair, just, and equitable management of all institutions serving the public directly or by contract; and the fair and equitable distribution of public services…".[14] Bike sharing systems predominantly serve young, white, well educated, affluent men - subgroups already at lower risk for those chronic diseases physical activity can help to prevent.[13,17,18] While Citi Bike member demographic information is not released to the public, "riders are mostly white, male, and live in households with six-figure incomes," according to one staff member.[12] More broadly, bike sharing systems simply do not reflect the diversity of the cities in which they are located and fail to reach those who could benefit from them most.[14,17]

This situation is a "looming concern" for many bike sharing programs, especially those receiving large government subsidies, but also for those privately funded systems, like Citi Bike, that position themselves as extensions of public transit rather than luxury items.[14] As bike sharing becomes more commonplace in the U.S., there is public and political pressure for systems to address the "equity issue," expanding service to

underserved neighborhoods and groups.[17,14] Many of them already attempt to – across the country, nearly all system operators have implemented some sort of equity or accessibility program targeted at low-income, "hard-to-reach" populations.[17] Out of 20 responses to a 2012 survey of system operators from the U.S. and Canada, 35% had existing stations sited based on equity reasons, 35% offered subsidized membership, 25% had annual membership payment plans, 25% assisted low-income members to obtain bank accounts and credit/debit cards (necessary for enrollment), and 25% waived a common security deposit hold on low-income users' credit/debit cards.[17]

Despite these efforts, uptake among equity initiative target populations has been minimal, blamed in large part on improper bike share station siting in low-income communities, prohibitive membership costs, credit/debit card requirements, and marketing materials that portray only the dominant culture.[17,13,14] Evaluators of one bike sharing equity initiative implemented in Minneapolis, Minnesota, found that environmental change alone, like the installation of a bike sharing station in a low-income community, may not be enough to lead to substantial and sustained changes in travel behavior among the target population.[19] Researchers suggested that advice and support at the individual and institutional level may be necessary, and that strategies to promote bicycling should focus on tackling deterrents and barriers to bicycle riding behaviors.[19] These include the danger and unpleasantness of cycling in traffic, the generally negative image of cycling as a childhood activity, and the perception of bicycles as being largely for leisure or sport rather than transportation.[19]

Citi Bike Discounted Membership Program

Originally conceived by the NYC Department of Transportation, in its original implementation, Citi Bike's equity initiative did not address the demographic, psychological, cognitive, or emotional factors related to physical activity or bicycling among low-income individuals, women, and people of color, who make up the majority of its target population. Among these groups, studies have shown the significance of various factors, from age, weight, and self-efficacy to social support, past exercise behavior, gender-based transportation responsibilities, and perceived risk.[20,21,17] Instead, like most equity initiatives that exist within the bike sharing industry, Citi Bike predominantly focused on cost and the mechanics of signing up for membership (i.e. resources for those without debit/credit cards).[17,13,14]

Since the system opened in 2013, Citi Bike has offered a $60 annual membership to every NYC Housing Authority (NYCHA) resident age 16 and older and to members of three Community Development Credit Unions (CDCU), which provide mainstream financial services to low-income populations in high poverty neighborhoods. Originally $35 less than a full-price annual membership (then $95), the discounted rate is now $89 less for NYCHA residents and select CDCU members ($149 full-price). Discount program members must pay the full $60 price of annual membership upon enrolling; the system does not offer a monthly payment option. Citi Bike and the NYC Department of Transportation (NYC DOT), which planned the implementation and oversees day-to-day operation of the system, promoted the discounted membership option through traditional means, such as brochures, newspaper and online articles; through social media; and through outreach events. NYC DOT distributed thousands of free bike helmets at nine giveaway events at

NYCHA developments during summer 2013, immediately after the Citi Bike system launched. While top-level NYCHA administrators were involved in the planning of these promotions, very few residents and only one local housing development manager were included in the discounted membership program outreach process.

Many bike sharing systems are criticized for seemingly profit-driven station placement that excludes low-income communities. As Morabia pointed out, for a bike sharing program to be more egalitarian, the distribution of bike docks needs to be thought out carefully; equity may be more easily achieved when high-rise housing projects are surrounded by affluent areas, rather than relegated to the periphery of the city.[22] Because public housing is interspersed throughout New York City, and throughout the Citi Bike service area, Citi Bike avoided such a critique, launching with nine stations placed directly on NYC Housing Authority property in Manhattan and Brooklyn, well integrated into the Citi Bike system. One of the country's densest bike share systems, more than 20 NYCHA housing complexes are within one-quarter mile of a Citi Bike station, providing convenient access to tens of thousands of potential discount program members. [FIGURE 1]

To date, the Citi Bike discounted membership program has not undergone internal or external evaluation.

Commented [EC2]: New sentence

Commented [EC3]: Moved this sentence to the top to introduce the topic of the paragraph.

Gaps in Data

Despite bike sharing's relatively recent arrival to the U.S., comprehensive research is available on bike sharing business models, industry trends, and user impacts, and research has consistently assessed user demographic data from individual systems.[1] Thanks to open data policies held by many bike share system operators, analysis of system utilization data has been widespread, particularly by bloggers, news reporters, cartographers, and data

visualization experts. However, only a small amount of academic research is available on the facilitators and barriers to public bike share system usage, and only two studies from the grey literature systematically address equity initiatives across various North American bike sharing systems.[17,13,14,23] Only one peer-reviewed article directly addresses bringing bike share to a low-income community in the United States.[1] One unpublished study by Thomas Stead, a graduate student of city and regional planning in Brooklyn, New York, reported on factors that deterred NYC Housing Authority residents from using the Citi Bike system in 2014.[24] To date, no research has been published on the actual use of a bike sharing system by those target populations of equity initiatives: women, low-income individuals, and people of color.

The primary objective of the present study was to determine who uses the Citi Bike discounted membership program and how those individuals use the Citi Bike system. Specifically, the study aimed to identify the following: (1) characteristics of Citi Bike discount program members, and how they differ from or are similar to general (full-price) members; and (2) characteristics of Citi Bike discount program members' trips, and how those trips differ from or are similar to general members' trips. By analyzing three months of Citi Bike utilization data, we hoped to make inferences about the success of the equity initiative and develop recommendations for program administrators.

Unfortunately, because the dataset provided did not include unique identifiers for each trip, such as a Citi Bike user ID number, it was impossible to gauge the exact number of members who used the Citi Bike system or the frequency with which they did so. The data indicated only the proportion of trips taken by general members and discounted members and the characteristics of those trips.

The study was conducted under the supervision of Philip Noyes, Director of Research, Planning, and Evaluation at the NYC Department of Health and Mental Hygiene Brooklyn District Public Health Office, who is part of a team studying the personal characteristics of all Citi Bike members.

Commented [EC4]: Added this sentence in response to Prof Crum's question re: who the "we" was in Methods section.

We hypothesized that a disproportionately high number of discounted member trips were taken by men under age 40 – those most likely to use a bike sharing system anywhere in the U.S.[1] We hypothesized that Citi Bike discounted members took less than 1% of all Citi Bike trips over the time period in question, since less than 1% of Citi Bike annual members enrolled through the system's equity program, based on information provided by NYC Bike Share. Additionally, we hypothesized that discounted members' trips were more likely to be taken to or from ZIP codes with NYCHA developments or high poverty levels, and that discounted members' trips were more likely to have the characteristics of recreational trips (as indicated by lengthy duration and occurring outside weekday commute times, for example).

METHODS

NYC Bike Share provided anonymized system utilization data for all trips taken from June 1, 2014 though August 31, 2014. NYC Bike share defines a trip as any time a Citi Bike member or casual user releases and returns a Citi Bike at any station within the system. Utilization data comprised: trip duration (in seconds), start date and time, stop date and time, start station number, start station name, start station latitude and longitude, end station number, end station name, end station latitude and longitude, bike ID number, user type (annual member vs. casual user), birth year, and gender. Publicly available to view

and download as Excel files from the Citi Bike website, monthly system utilization datasets do not include personally identifiable information (e.g. Citi Bike User ID number).

For the purposes of this study, the utilization data provided to us by NYC Bike Share included one additional variable: discount type. In an extra column within each dataset, discounted members were identified as "NYCHA CDCU" or "CDCU New Member;" general (full-price) members were left blank. A "NYCHA CDCU" designation meant that the Citi Bike member was a NYC Housing Authority resident or Community Development Credit Union member before Citi Bike launched in May 2013, and purchased a discounted Citi Bike membership using a personal discount code related to his NYCHA or CDCU identification number. A "CDCU New Member" designation meant that the Citi Bike member joined a partnering Community Development Credit Union after Citi Bike launched and, in doing so, received from credit union staff a code to purchase a discounted Citi Bike membership.

NYC Bike Share also provided a list of 332 Citi Bike station names and their corresponding ZIP codes, which allowed us to add two new columns to the Excel data files: start station ZIP code and end station ZIP code. With this information we were able to analyze trips by neighborhood, rather than simply on an individual station level.

Data Cleaning

We first consolidated the three Excel files (June, July, and August 2014) into one dataset, which we uploaded into SPSS version 22. For ease of analysis, we recoded text variables into numerical variables, such as user type (Subscriber/annual member=1, Customer/casual user=0) and discount type (general member=0, NYCHA/CDCU=1, and CDCU New Member=2). We then created a new dichotomous variable that would allow us

to compare all general members (0) with all discounted members (NYCHA/CDCU and CDCU New Members=1). We recoded the variable birth year into age groups, allowing for easier comparison to existing data. The new variable grouped Citi Bike riders into the following age brackets: 16-24, 25-44, 45-64, 65+, which is the default age categorization used by the NYC Department of Health and Mental Hygiene.

Based on start station ZIP code and end station ZIP code variables, we added two new variables identifying the poverty level of each trip's start and end station locations (high poverty=1, low poverty=0) and whether start and end stations were located in neighborhoods that included at least one NYCHA development (NYCHA=1, no NYCHA=0). High poverty ZIP codes were selected from a list developed by the United Hospital Fund, and included Bedford-Stuyvesant (11216, 11221) and Williamsburg, Brooklyn (11211); and Chinatown (10002) and the Lower East Side (10009) in Manhattan.[25] We gathered from the NYCHA website those New York City ZIP codes that contain at least one public housing development, included: Downtown Brooklyn (11021), Fort Greene (11205), Bedford-Stuyvesant (11216, 11221), Williamsburg (11211), and Boerum Hill, Brooklyn (11217); as well as the Lower East Side/Chinatown (10002), East Village (10009), and Chelsea (10011, 10001) in Manhattan.

Using the SPSS Date and Time Wizard, we transformed the start and end time variables, which originally included both date and time consolidated in one variable, into multiple variables: start month, start day, start hour, end month, end day, and end hour. Further, we created a new variable that identified any trip that started from 7am-10am or 5pm-7pm on a Monday, Tuesday, Wednesday, Thursday, or Friday, which we labeled as a

"weekday commute time" trip. A trip that started any other time, including on the weekend, we labeled as being taken "outside commute time."

Analysis included descriptive statistics to examine the characteristics of general and discounted members and their trips. We used cross-tabulations to compare members' characteristics and trips.

RESULTS

Sample

From June 1, 2014 through August 31, 2014, Citi Bike riders took a total of 2,871,545 trips. During those three months, annual members took 2,497,653 trips (87%) and casual users, who purchased 24-hour or 7-day Citi Bike passes, took 373,892 trips (13%). Because Citi Bike's equity initiative applies to annual members only, we eliminated from the dataset any trips taken by casual users. This resulted in 2,497,653 trips to analyze, taken only by full-price and discounted annual members.

Of those trips, we considered 3,100 (.1%) to be "unrealistic," and eliminated them from the dataset. "Unrealistic" trips lasted under 60 seconds or over three hours. A trip lasting under 60 seconds likely represents a user releasing and immediately re-docking a bike, not taking an actual trip. A trip lasting over three hours likely represents a bike that was not properly docked after a shorter trip, or a bike that was lost or stolen. That brought the "realistic" annual member trip total to 2,494,553, which became our dataset for analysis moving forward. [TABLE 1]

Discounted Member Population

Of all realistic trips taken by annual members, about 76% were taken by men and 24% by women. Compared to general member trips, women took a higher proportion of

discounted member trips, though men still took the majority of trips. Among discounted members, women took 32.4% of all trips – nearly 1/3 of discounted members' trips. Among general members, women took 23.8% of trips – less than 1/4 of all general members' trips. [TABLE 2]

Overall, most Citi Bike trips were taken by 24-44 year-olds (66.3%) and 45-64 year-olds (24.7%). But, when comparing general and discounted members, the proportion of trips taken by each age group varies slightly. Among general members, 25-44 year-olds took 66.4% of trips. But, among discounted members, 25-44 year-olds took only 52.7% of trips – 13.7% fewer. Older people made up much of that difference: 45-64 year-olds took 24.6% of general members' trips, but 35.3% of discounted members' – 10.7% more. And while those age 65 or older took 1.5% of general member trips, among discounted members they took nearly twice that – 2.9%. Also, the proportion of trips taken by Citi Bike's youngest members varied slightly between general and discounted members. While16-24 year-olds took 7.6% of general member trips, they took 9% of discounted member trips – 1.6% more. [TABLE 3]

Among women in particular, older riders took a higher proportion of discounted member trips compared to general member trips. Women under 45 took 77.6% of all trips taken by general member women, but only 54.3% of all trips taken by discounted member women – a difference of 23.3%. Women age 45-64 took 21.4% of general member women's trips, but 40.6% of discounted member women's trips – 19.2% more. The oldest age group, women age 65 or older, took .9% of all trips taken by general member women, but 5.1% of all trips taken by discounted member women – more than five times as many.

Discounted Member Trips

Discounted members took 15,427 trips in June, July, and August 2014, .6% of all Citi Cike trips taken during that period. Overall, most Citi Bike riders used the system on weekdays. In June, July, and August, 77.5% of general members' trips and 74.8% of discounted members' trips were taken on a weekday (Monday through Friday). Citi Bike trips are usually short; general members' trips were slightly shorter than discounted members' trips during summer 2014. The mean trip length was 12 minutes 53 seconds (772.86 seconds) among general members and 13 minutes 21 seconds (801.35 seconds) among discounted members, a difference of only 28 seconds. The median trip length was 10 minutes 13 seconds (613 seconds) among general members and 10 minutes 53 seconds (653 seconds) among discounted members, a difference of 40 seconds. [TABLE 4] Discounted members took a higher proportion of trips outside the "weekday commute time" (65.1% compared to 58.2%). [TABLE 5] No difference in average trip duration appears when comparing trips that started during and outside weekday commute times.

Almost all trips taken from June through August 2014 started and ended at different Citi Bike stations; hardly any trips started and ended at the same station. Among general members, only 2% of trips started and ended at the same station. Among discounted members the number was only slightly higher at 2.8%. Trips that start and end at the same station are generally thought to be recreational trips, taken for exercise or pleasure, but not for transportation. Among trips taken by women, discounted members took a higher proportion of trips that started and ended at the same station than general members (3.6% compared to 2.3%).

A higher proportion of discounted member trips than general member trips started

in a ZIP code that includes at least one NYCHA development (51.1% compared to 29.9%). [TABLE 6] Among women, a higher proportion of discounted members' trips started in a ZIP code that includes at least one NYCHA development (55.8% compared to 31.5%). Overall, 38.8% of all trips taken by discounted members started in a high poverty neighborhood, while only 11.1% of trips taken by general members did. [TABLE 7] No matter the day of the week, a higher proportion of trips taken by discounted members started in a high poverty neighborhood – 36.8% on weekdays (compared to 10.2% by general members) and 44.6% (compared to 14.5% by general members) on weekends. (High poverty neighborhoods are determined by the United Hospital Fund codes and include Bedford-Stuyvesant, Williamsburg, Chinatown, and the Lower East Side.)

Conclusion

Main Findings

This study examined the characteristics of 15,427 trips taken by discounted Citi Bike members during three months of operation in 2014, and compared them to those of nearly 2.5 million trips taken by general members over the same period. We found that discounted members took close to but fewer trips than expected, taking .6% of all trips while making up an estimated 1% of Citi Bike's entire annual member population. Overall, discounted member characteristics followed the same tendencies as general member characteristics in terms of gender and age: men age 25-44 took a higher proportion of Citi Bike trips than other groups, whether they gained access to Citi Bike through a full-price or discounted membership. Women and older people, though, took a higher proportion of discounted member trips than general member trips, particularly women age 45 and older. Trips taken by discounted members were similar in duration to those taken by general

members – short, were just as likely to be taken on a weekday, and were just as unlikely to start and end at the same Citi Bike station. A substantially higher proportion of discounted member trips started in a high poverty neighborhood or a ZIP code that contained at least one NYCHA development.

Discounted Member Population

The demographics of Citi Bike discounted members, according to the utilization data we analyzed, reflects the population from which discounted members are drawn – a population that leans more female and older than New York City's general population. According to 2010 U.S. census data, women made up 52.2% of New York City's population.[26] However, in 2011, the year from which the most recent housing data is available, 60% of NYCHA's 486,349 residents were women.[27] So, while women took 23.8% of all general members' Citi Bike trips during summer 2014, it makes sense that among discounted members – largely NYCHA residents, who are predominantly female – women took a higher proportion of Citi Bike trips (32.4%). Similarly, while 12.1% of New York City residents are age 65 or older, 13.5% of NYCHA residents fall into that age bracket.[26,27] Again, this slight difference appears in Citi Bike utilization data, which shows that members age 65 and older took 1.5% of general member trips, but 2.9% of discounted member trips. Finally, in NYC public housing, 23% of women are 45 years old or older (only 10% of men are). However, of all trips taken by female discounted members in summer 2014, 45.7% were taken by women age 45 and older, showing that older female discounted members are disproportionately active in the Citi Bike system.

Discounted Member Trips

Contrary to our hypothesis, Citi Bike discounted members' trips did not have the

characteristics of recreational bike trips or trips taken for leisure, e.g. longer trip duration, starting and ending at the same station, and starting outside traditional commute times. Instead, discounted members' trips were quite similar to general members' trips. Among both groups, median trip duration was just shy of 11 minutes, about 75% of trips were taken on weekdays, and only around 2% of trips started and ended at the same station. While discounted members did take a slightly higher proportion of trips outside the weekday commute time, discounted members appear to have used the Citi Bike system for transportation, rather than recreation or leisure. Additionally, the proportion of discounted members' trips that started in high poverty neighborhoods or those neighborhoods with at least one NYCHA development, which was substantially higher than the proportion of general members' trips that started in these areas, suggests that Citi Bike discounted members do, in fact, come from the populations NYC Bike Share intends to serve through its equity initiative.

Discussion

An analysis of three months of Citi Bike utilization data showed that discounted members – self-selected participants in Citi Bike's equity initiative – took only .6% of all Citi Bike trips in summer 2014. Without assessments of similar bike share equity initiatives implemented within the U.S. available, it is impossible to compare this number to other systems' efforts. However, it is clear that there is ample room for expansion of the Citi Bike discounted membership program, especially considering the large number of people eligible from within NYCHA, and, to a lesser extent, Community Development Credit Unions. We recommend that NYC Bike Share develop measurable goals for the growth of its equity initiative based on this initial analysis. Additionally, we recommend NYC Bike Share

encourage system operators across the country, many of which are owned by the same parent company, to adopt similar evaluation plans, standards and metrics.

Utilization data showed that during summer 2014 women took 23.8% of Citi Bike general member trips and 32.4% of discounted member trips, though in 2013 researchers from Hunter College observed that only 18% of New York City bicycle riders were female.[28] A number of studies have explored the reasons for low uptake of bicycling among women, citing reasons including complex travel patterns, having to make more child-serving trips, as well as concerns about traffic safety.[29,21,30] While not gender equitable, Citi Bike utilization appears to be *more* gender equitable than non-Citi Bike bicycle commuting in New York City, and *most* gender equitable among discounted members. This difference may be a reflection of overall population differences, where women make up a larger proportion of the NYCHA population, but it highlights the fact that despite personal barriers, gender-based responsibilities, and risk perceptions, there is some demand among low-income women for Citi Bike – particularly those women over the age of 45. Exploration of ways to further engage low-income women in this age bracket is warranted.

A report produced by the Mineta Institute at San Jose State University showed that of four major established bike sharing systems in the U.S. and Canada they examined, all catered disproportionately to the rich.[13] In all four cities, low-income cohorts represented a smaller share of the bike share member population than they were of the total city population, while high-income cohorts did just the opposite.[13] Nationally, though, those with annual incomes under $20,000 reported having ridden a personal bicycle most frequently in the last year, both for recreation and transportation.[9] Yglesias poses reasons for this discrepancy: personal bicycles are already relatively affordable and a thrifty travel

option for the poor, bike sharing systems are not reliable enough for low-wage shift workers, and bike share is an amenity that low-income families, who already spend a hefty amount on transit, find it easy to go without.[31] Yglesias described bike sharing as a "high-end recreational amenity that people spend money on when they have money to spare."[31]

With this, we hypothesized that Citi Bike's discounted members would represent the few NYCHA residents and CDCU members who could spare additional income for occasional recreational riding, and their trips would have the characteristics of recreational or leisure trips. However, analysis of Citi Bike utilization data showed that discounted members' trips were almost identical to trips taken by general members: short, taken on weekdays, and starting and ending at different stations (point-to-point). Despite the very small percentage of low-income individuals and people of color who report riding a bicycle for transportation in New York City, it appears that Citi Bike discounted members do, in fact, use the system for transportation rather than recreation.[32,17,33] In his research on deterrents to Citi Bike use among NYCHA residents, Stead found that the top reason residents cited for not having used the bike sharing program was that people were simply used to their routine.[24] We recommend NYC Bike Share offer NYCHA residents and low-income New Yorkers opportunities to try riding a Citi Bike specifically for transportation in order to understand the efficiency of bicycle commuting as well as how the system could fit into their current routine, benefitting them financially and physically.

Limitations

Because the dataset provided by NYC Bike Share did not include unique identifiers for each trip, such as a Citi Bike user ID number, it was impossible to tie trip data to a certain Citi Bike member or to gauge the frequency with which certain Citi Bike members

used the system. Neither could we determine how many separate individuals took these trips. The data provided does not tell us how many members used the system or how frequently they did so, but only the proportion of trips taken by general members and discounted members from June through August 2014.

The use of utilization data limited what could be studied, particularly the race/ethnicity of Citi Bike members, which is not included in Citi Bike utilization datasets. Because over 95% of NYCHA residents are people of color and select Community Development Credit Unions are located in low-income communities consisting predominantly of people of color, discounted membership was used as a proxy for race/ethnicity. In addition, as Citi Bike annual member keys can be passed between individuals, it is likely that a small number of trips were made by individuals with different demographic profiles to those who registered. Finally, having data for only a three month period meant it was not possible to study temporal trends, particularly as usage levels are likely to be highly affected by the seasons, and may impact general and discounted members' use of the system differently.

Utility

Many low-income individuals, women, and people of color, who make up the vast majority of NYC public housing residents, are insufficiently physically active and overweight or obese, suffering disproportionately from related conditions. [27,32,34] Simultaneously, while low-income households have been found to have slightly shorter commute distances, they still spend significantly more time commuting than their non-poor counterparts, thanks to slower speeds on public transit.[35] Active transportation has the potential to provide much-needed physical activity while offering an efficient

transportation option to those who could most benefit from both. Bike share can help achieve health and transportation equity, but first must effectively address its own inequity.

Some bike share system operators admit that planning or implementing programs to address equity is premature, as they are squarely focused on establishing functional systems that don't lose money, as they often do.[17,36] By better understanding those underserved populations who select to use a bike sharing system, and how they actually use the system, we believe that bike share operators will be able to more efficiently apply their limited resources to implement and expand effective equity initiatives. Additionally, this study will contribute to a limited body of literature on active transportation habits of low-income groups, and to a small but growing body of literature related to bike sharing, a rapidly expanding industry.

___This paper is unacceptable.

Reason for above choice:

Comments for NAME REDACTED paper on bedbugs:

– I had a great time reading this draft of the paper. I found it to be much more organized and clear, and I can see a lot of work went into this current version. You are well on your way to having a publishable article! See my comments below. These are the main comments I would like you to address in the response to reviewers.

Abstract –

The abstract is generally good, but more detail is needed in Methods regarding size of sample, the fact that it is a survey of adult residents, clarification regarding what you examined (risk factors for infestation; range of potential health outcomes); and statistical methods used (logistic regression).

In conclusion, the first sentence conclusion is not sufficiently apparent to readers. What supports apt-to-apt travel, and what supports hitchhiking?

Introduction –

Generally, a nicely written section. I find the placement of mental stress before physical health (where more is published) to be odd and would recommend switching the paragraphs. See one other minor comment in tracked changes document.

Methods –

Good section! Mostly very minor edits. I had two questions for you to consider and one possible re-wording suggestion.

Questions:

(1) The question pertains to new diagnoses of asthma (see notes). Do you think it is worthwhile to retain, given the extremely rare occurrence of new-onset asthma among adults? Might the issue of "genesis" of asthma be better studied among children? I do agree with the inclusion of ever diagnosed and ED visits – to examine asthma exacerbations.
(2) After reading your Methods section, I don't expect to see health variables (such as depression, first diagnosis of depression, NSPD, etc) as predictors of bedbug infestation, yet they show up in table 1. Either explain that you are also examining health predictors or take out (which is my recommendation). In particular, the rationale for looking at first occurrence of depression as a predictor of bedbug infestation is not clear to me.

Re-wording suggestion:

I suggest you re-word the section on why you forced the age and number of household members into the final model.

Results –

In paragraph about fully-adjusted model, it may be worth pointing out in a sentence which associations were no longer apparent after SES and other adjustments. I think this is particularly noteworthy for race/ethnicity and number of children in the HH.

Discussion –

Excellent re-write! I think the structure of the discussion is now quite good. I have some edit suggestions for clarity and I suggest you try and reduce the total length of the limitations section (currently 5 paragraphs) and perhaps organize it by design issues (i.e temporality), measurement issues (bit sensitivity, unmeasured variables, residual confounding), and perhaps only a brief mention of external validity.

Reason for above choice:

, you have done a great job. My main comments (as also found embedded in the document itself) are:

1. I would reorder the introduction to match the analysis – so prevalence, risk factors, health outcomes, why our study.

2. I (also) think that the health outcomes should not be included as predictors, so should not be in Table 1 or 2.

3. I think alcohol drinking should be thought of as a predictor rather than a health outcome (perhaps – although could also consider dropping it) – I thought it was meant to counterbalance the findings with sugar sweetened beverages?

4. You need to add the sample size to the abstract and to the methods section.

5. The limitations section should be shortened to may be 2 paragraphs with a clear order of limitations – probably related to first prevalence estimate, second predictors, third health outcomes to match the flow of the paper. It might also be worthwhile to add a short paragraph about the strengths of this study (generally like to include both strengths and limitations in the discussion section).

All in all – you've done a great job! - Heidi

Self-reported bedbug infestation among New York City residents: prevalence and risk factors, 2009

Dear

You have a lot of great work done here already. I think most of your analyses are quite good – with a few minor exceptions that I point out in the body of the paper. What I see the paper needs now is some re-organization and re-crafting of text to simplify concepts and language, being more systematic is laying out thought processes and measures, and cutting back on talking beyond your what your data can tell you.

As the next version is your "final" version, you also need to make some simple structural additions. Your final paper should have a title page (regular 12 point font title, your name, date, abstract and text word count, and target journal), an abstract page, and all tables should be at the end of the paper, not embedded in the middle of the text. Also, this particular draft is missing table 2 – a key table.

I second Lorna's comments. This paper has come a long way and you have clearly put a lot of work into it. Upon rereading the methods section, I agree with Lorna that it could still be tightened/reorganized. I like the idea of removing the mental health outcomes as predictors of bedbug infestations, and leaving these only as potential outcomes from bedbug infestations. This will then streamline how to present the methods, and will be easier for the reader to see the bigger picture. Then the methods, results and discussion sections can all go in the same order: 1. Prevalence 2. Predictors of bedbugs 3. Outcomes from bedbugs.

I also agree that you need to more carefully differentiate in the discussion section between conjecture and discussing how the results from this study compare with other studies.

Nice work!

HeidiBackground

Bedbug infestations, once a common problem worldwide, virtually disappeared in the

industrialized world after World War II. In the past 5-10 years, however, reports of bedbug

infestations in urban centers have risen precipitously, with many urban areas around the world reporting double digit increases.[1-3] Prevalence appears to be widely divergent both within the United States (U.S.) and globally, and bedbug complaints to New York City's (NYC) 311 telephone line began increasing sharply in the past decade, from 537 in 2003 to 1,839 in 2004, following a steep gradient to 10,985 in 2009.[4]

Health Consequences

To date, dermatological presentations and vector competency for transmitting infectious diseases have dominated research on health outcomes caused by bedbugs. Known health effects of bedbugs are primarily limited to dermatological bite reactions of blisters and rashes. Bites can itch, which may lead to secondary infection from scratching,[5] and in rare cases, anaphylactic shock.[6, 7] Skin disease and exacerbated skin conditions have frequently been linked to mental stress,[8, 9]. One study found that among households with bedbugs, residents reported experiencing mental health symptoms in relation to infestations, including: sleeplessness (29%), anxiety (20%), emotional distress (22%) and stress (14%).[10] These symptoms are also uniformly acknowledged among field practitioners and pest control professionals. Delusional infestations have been reported as both a purely psycho-social phenomenon and an immediate aftershock of cleared infestation.[11] Anecdotes of social ostracism – from job loss to dating barriers – have been noted in social networking outlets and other media.[12-14]

Commented [LT1]: From LORNA: You don't demonstrate "divergence", so to me this is a non-sequitor statement unless you either (1) show data from an urban center that had no increase or a smaller increase, or (2) change first clause of the sentence to not focus on divergence.

I also think it would help your paper overall if you added a sentence here about the difficulty of tracking trends due to reliance on imperfect administrative data, such as tel calls. That's what makes YOUR data source so unique.

From HEIDI: I agree with Lorna – would take out the divergent part of the sentence and conclude with a sentence about difficulty in measuring.

Commented [LT2]: From LORNA: Moved your last sentence up to front here –it felt repetitive and out of place at end – perhaps it works as a topic sentence instead.

From HEIDI – I agree with Lorna, had noticed this didn't fit earlier, feel it flows better this way.

Commented [LT3]: From LORNA: Because you can't substantiate this, particularly as phrased ("uniformly…"), I would delete. I also don't think it strengthens your paragraph, even if largely thought to be true (mind you, anecdote is highly valuable in hypothesis generation….it just doesn't work in peer review papers).

From HEIDI: Again, I agree with Lorna, had similar thoughts on this sentence .

Commented [LT4]: From LORNA: Awkward phrasing – "..Perceived infestations"? "…Imagined infestations"?

Commented [LT5]: From LORNA: This anecdote works because you have citations and you frame it as anecdote.

Unlike cockroach allergens, there is little evidence for an association between bedbug infestation and asthma onset or exacerbations,[15] although research has been limited. Bedbugs have also proven to be unlikely transmitters of infectious diseases, probably through a combination of minimal blood transfer during feeding and barriers to viral replication within the insect itself,[16-18]. Two possible exceptions may include Hepatitis B,[5] and recent hypothesis that bedbugs could serve as a reservoir for MRSA.[19]

Commented [NIR6]: I may not be right, but this MRSA thing seems much less established than Hep B, which at least has some investigation of transmission vehicle plausibility. MRSA was just found in bedbugs on folks with MRSA, and nothing was discussed about transmission in the paper, except that punctured skin might be vulnerable (not quite a bedbug transmission thing.) Am I reading the right article here? Anything I'm missing?

From LORNA: NO, seems right to me.

An indirect health impact of bedbug infestations may be the use of pesticides in bedbug control. Home extermination is one of the leading causes of pesticide exposure in urban settings.[20] Even relatively low doses of residential pesticides are associated with childhood leukemia[21] and with the exacerbation of conditions such as diabetes.[22] Further, these risks increase with cumulative exposure. In addition, bedbug hardiness in the face of extermination efforts may increase risk of pesticide misuse or over-use. Risk from bedbug extermination is already evident; 111 acute pesticide poisonings related to bedbug extermination were reported from 2002 to 2010 in the US as a whole, with more than half (58%) of these coming from NYC residents alone.[23]

Commented [NIR7]: Do I need to cite this?

Little is known about risk factors for bedbug infestation. Bedbug transmission has largely been assumed to happen via "hitchhiking" – the ability of bedbugs to sequester themselves on clothing or personal items, which are then moved by their owners to new locations. Human transfer may occur while visiting infested places outside the home, or residents may unwittingly

introduce bedbugs into their homes by acquiring infested furniture, clothing or toys.[24] Historically, research has suggested that low-income households have greater risk of other pest infestations (such as mice or cockroaches) due to overcrowding, poor housing stock, and implied housing management issues. More recently, field reports from one study proposed apartment-to-apartment bedbug travel via structural egress points such as hallways or electrical conduits.[24] Additional studies on determinants for building-level transmission would be useful in generalizing these findings.[25]

Given these hypothesized mechanisms for bedbug transmission, levels of social contact, differences in local travel and activity, and risk level of those in the subject's building or social network may also play a role. These risks may, in turn, depend on demographic or environmental factors, which are largely unexamined in relation to bedbug infestation. This investigation (1) estimated the prevalence of bedbug infestation using self-reported data from a community-based municipal survey conducted by New York's Department of Health and Mental Hygiene (NYC DOHMH) in 2009, (2) examined individual demographic and behavioral characteristics, household composition characteristics and building/neighborhood environmental characteristics as possible determinants of infestation, and (3) explored possible health outcomes of infestation.

Commented [NIR8]: Conduit is material, conduits is function. Will anyone know the difference or should I choose a different word – I want the material…

From LORNA: Not everyone will get it, but I think the terminology you select here is OK.

Commented [LT9]: I would delete this sentence – save such a recommendation for the Discussion.

From HEIDI: Again I agree with Lorna, had a similar reaction to this sentence the last time I read it.

Commented [LT10]: From LORNA: I suggest deleting these two sentences. Go straight into what you aim to show. The reader is going to struggle to track what you are listing and the conjectures you are making here in your attempt to be succinct. I don't think it adds much.

See how I suggest structuring the paragraph – you may not like the numbered approach (that's fine) but you should start to give the reader a sense of the 3 aims and the structure they will see throughout the rest of the paper…prevalence first, risk factors for infestation second, then health outcomes third. You can leave details of which health outcomes to Methods section.

Also, I think "…looked at" is too colloquial.

From HEIDI: I think these are good suggestions.

Methods

Data Source

The Community Health Survey (CHS) is an annual representative cross-sectional telephone survey of NYC adults aged 18 and older. This survey is administered by the NYC DOHMH and collects self-reported measures of health, behaviors and demographic characteristics using a neighborhood stratified random sample. Details of the study and sampling scheme are reported elsewhere.[26]

In this analysis, we used data from the 2009 CHS, which had approximately 125 questions. Responses were collected using a computer assisted telephone interview format. Interviews were conducted in English, Spanish, Russian or Chinese. Group residences, such as college dormitories, and homes of families with both landlines and cell phones were excluded. Among households agreeing to participate, one adult was selected at random to complete the survey, which took an average of 25 minutes to complete. The response rate was 34% for landline and 50% for cell phone, with a cooperation rate of 88% and 97%, respectively. The survey and method for gathering informed consent was approved by the DOHMH Institutional Review Board. The current analysis was deemed exempt from review by the CUNY Hunter College Institutional Review Board.

Measures

We used CHS responses to explore prevalence, predictors of self-reported bedbug infestation, and the extent to which bedbug infestation predicted key health outcomes. Bedbug infestation

Commented [LT11]: From LORNA: This section seems jumbled in its order. I suggest you follow the (1) prevalence, (2) risk factors for infestation, (3) health outcomes of infestation order. Save specificity of health outcomes until third paragraph because otherwise reader starts to nit-pik the selected list (why this, and not that) prematurely. You want them to wait until the designated section to think critically about this list.

From HEIDI: I think this is a good suggestion. I think this section is much clearer now, but it could still use some reorganization – I like the idea of listing these later.

was measured as a dichotomous response to: "During the past 12 months, have you had a problem with bedbugs in your home that required an exterminator?" In separate analyses, health outcomes examined included current depression, first diagnosis of depression in last 12 months, NSPD, heavy alcohol drinking, binge drinking, ever diagnosed with diabetes, ever diagnosed with asthma, diagnosed with asthma in the past 12 months, and asthma-related emergency department visits in the past 12 months. NSPD was determined by the standardized K6 scale. Diabetes, asthma and depression were determined by dichotomous answers to standardized questions modeled after the Behavioral Risk Factor Surveillance System for self-report of diagnosis by a health professional. (e.g., "Have you ever been told by a doctor, nurse or other health professional that you had *condition x*?"). Heavy alcohol drinking was defined as >2/day for men, >1/day for women, and binge drinking was defined as reporting 5 or more drinks on at least one occasion in the past 30 days.

Predictors of bedbug infestation explored included age (grouped 18-24, 25-44, 45-64, 65+ years), sex, race/ethnicity (white, black, Asian, Hispanic; "other" [n=175] was recoded as missing), nonemployment (combining homemaker, student and retired and unemployed/unable to work), education (less than high school, high school graduate, some college/technical school, college graduate), household poverty status (<200% of Federal Poverty Level [FPL] vs. >=200% of FPL), marital status (married/member of unmarried couple vs. divorced/widowed/separated/never married), country of nativity (U.S. vs. foreign born). Self-perceived health (excellent/very good/good vs.fair/poor) was included as a potential

Commented [LT12]: From LORNA: Put this paragraph after risk factors for infestation

Commented [LT13]: From LORNA: I suggest throughout your manuscript you address individual level, then household level, then neighborhood level characteristics, in that order.
BTW, marital status is individual level…it is not a direct measure of household make up, as you indicate in table 1 (a person could be married and not living together, or divorced and shacking up).

I also think you should not examine health status variables as predictors of bedbug infestation at all…too tangential in terms of plausible mechanisms and didn't really show anything useful, such as self-reported health, depression (all 3 measures) , alcohol use. I think it detracts from the elegance of your paper rather than adds to it.

Sex behavior is OK, and I will accept sugar-sweetened beverage drinking if you justify it more clearly in Methods section. These are all respondent-level.

Household level is total family size, HH income (decide if you want to refer to it as HH income or HH poverty and be consistent….and you do need to refer to it as "household" income throughout because it is not the respondent's income level but the HH level), total number of children, and number of children under 6. I am confused about whether you examined total number of children or not – you refer to it in text but not in tables. If you examined it, you need to add to Table 1.

Commented [LT14]: From LORNA: OK to add citation here instead of describing where cut-offs come from

mechanism for dermatological presentation, and for a potential confounder of infestation influence on mental health outcomes. Environmental predictors included neighborhood poverty levels (high, medium, low – based on tertiles of percent of residents living with incomes <200% FPL), and number of units in building (1-2 units, 3-9 units, 10-49 units and 50 or more units). Household makeup variables consisted of number of children by agegroup(?) (<6 years old, 6-12 years old, 13-17 years old), and total household size (recoded to 1, 2, 3 and 4 or more). Finally, we explored behavioral predictors: number of sex partners (0-1, two or more), and any recent physical activity ("During the past 30 days, other than your regular job, did you participate in any physical activities or exercises such as running, calisthenics, golf, gardening or walking for exercise?"). We included number of children under six years old in the model as an opportunity to explore the possible mediating effect of the pest management regulation in grade schools compared with non-regulation of day care. As an exploratory measure, we also examined sugar sweetened beverage consumption (average consumed per day; none, less than one, one or more).

In models exploring the association between bedbug infestation and select health outcomes, we also examined insurance status (private, Medicare, Medicaid/Family Health Plus, other, uninsured) as a possible confounder of health outcomes through differentiated levels of diagnosis.

Commented [LT15]: From LORNA: Unclear text and mechanism – see my comment about dropping.

Commented [LT16]: From LORNA: Suggest dropping the sentence about neighborhood and indiv income not being correlated. Yes, you should look at that, but your data show that they each independently contribute information, so I don't think you need to state this to demonstrate indirectly that you assessed for collinearity.

Commented [LT17]: From LORNA: I am confused – did you look at both total number of children (if so, where are the data) AND number of children under 6 years old? I think you cannot be so specific here in Methods about your hope to use this variable to measure differences in pest mgmt. between school/institution settings. There are many possible ways a risk may be elevated in younger kids (day care, child care, sharing toys, greater propensity to use second hand furniture) and many ways it could be biased reporting (greater fear among parents of young kids) etc. Better to lay out what you look at here, and be a little more systematic in discussion about possible reasons for the observed association.

Commented [LT18]: From LORNA: In this instance, you need to articulate why….reader will be totally confused by addition of this one. I think this is a different issues than household composition, which doesn't need as detailed justification.

Data Analysis

Analyses in this study were performed using SAS version 9.2 (SAS Institute, Cary, NC). DOHMH-developed weighting strategies were applied to adjust for sampling methodology, adult telephone usage (landline only, landline and cell and cell only), and weight results to reflect age, gender and race distributions of neighborhoods (zipcode aggregations known as United Hospitalization Fund neighborhoods). To identify factors associated with bedbug infestation, covariates were individually analyzed in logistic regression using a chi-squared test. Those with significant p-values were included in a final multivariate logistic regression model aimed at identifying independent predictors of infestation.

Commented [LT19]: Cite NYC Housing vacancy survey here – no need to describe it)

Commented [LT20]: If you actually did not include some variables due to collinearity, describe your process at the end of this paragraph. How did you determine – be a little more specific.

To characterize potential health effects from bedbug infestation, we generated a separate model for each health outcome examined. Base models initially each had bedbugs as the only predictor. We then examined the influence of other covariates on this association to detect and adjust for potential confounding. Those covariates effecting a 10% change in the coefficient for the association between bedbug infestations and the health outcome were retained in the model. For highly collinear variables, we selected covariates for inclusion or exclusion based on relative strength and model fit.

Commented [CHC21]: The log odds that is the log odds of the outcome not really the predictor.

Commented [LT22]: Again, I don't exactly know what you mean by unique contribution, relative strength and model fit….I THINK you mean that you had to make some decisions on collinear variables , so this is how you did it. I suggest text changes – tell me if I changed the meaning of what you did.

Results

Prevalence and Distribution

In 2009, 6.7% (95% CI 5.9-7.5) of adults self-reported a bedbug infestation requiring an exterminator in the past year. (Table 1) By borough, Brooklyn had the highest level of

infestation (8.9%) and Staten Island the lowest (2.5%). The distribution of bedbug infestations showed an inverse relationship with age of the respondent, ranging from 10.5% for those 18-24 years to 3.5% for those 65+. Hispanic residents had the greatest proportion of reported infestations (10.5%) and white residents had the lowest (3.8%, p=<0.01). Those with low household income (<= 200% of FPL) had significantly higher reported infestations compared with those with higher income, and this negative association pattern was consistent with two other measure of socioeconomic status: education (12.4% less than high school through 4.5% for college graduate, p<0.01), and neighborhood poverty levels (10.9% for high poverty neighborhoods and 3.2% for low poverty neighborhoods, p<0.01).

Overall, rrespondents with children under 18 years of age reported bedbugs more often than those without children, with an observed positive gradient of association based on number of children. When children were categorized by age, the gradient for number of children was stronger among younger ages. Likewise, prevalence of infestation increased with the number of adults and total size of household showed a positive gradient with infestations. Whle not statistically significant, respondents reporting having no or one sexual partner appeared to have fewer infestations than those having two or more (6.7% versus 10.5%, p…). The differences in infestations among those with any measures of asthma were not significant. Those who scored positive for NSPD had higher levels of infestation (13.2% with positive scores versus 6.3% who did not score positive), as did those with diagnosed depression (9.4% with any diagnosed depression versus 6.3% with no diagnosis) although depression lacked statistical

Commented [LT23]: From LORNA: Not shown….

Commented [LT24]: From LORNA: Did you look at this?

significance. A positive gradient of bedbug infestation was evident for those consuming sugar-sweetened beverages (4.5% for none, 6.9% for less than one per day, and 9.7% for one or more) and for physical inactivity in the past month (8.9% for those who were inactive versus 5.9% for those who were active).

Commented [LT25]: From LORNA: Suggest dropping.

From HEIDI: I agree with Lorna about dropping the mental health stuff as predictors – it confuses the paper, I like it better with these just as outcomes, but don't think you need to drop the sugar beverages.

Predictors of Bedbug Infestation

In the final adjusted model containing factors significant in bivariate analysis, only younger age of respondent (18-24 compared to 65+, adjusted odds ratio [AOR] 2.1; 25-44 AOR 1.7), household income below FPL (AOR 2.7), household size of four or more compared with one (AOR 1.7), and high neighborhood poverty (AOR 1.8) were significant positive predictors of bedbug infestation. Living in a 1-2 units in building compared with 50 units or more was protective (AOR 0.4), compared to living in a building with 50 or more units. Sugar-sweetened beverages, however, retained the same odds ratio as in the bivariate model, with marginally wider confidence intervals (AOR 1.8, 95% CI 1.2-2.6), with only the associations in age categories attenuated. On further investigation, among age group 25-44, distribution for sugar-

Commented [W26]: If comparing 1-2 units, all are significant, but it's really the 1-2 units that's the outlier. The rest are basically the same. Is that what you mean? Making 1-2 units the referent? I think maybe we discussed this with the adjacency discussion, but maybe I'm not understanding what you mean.

sweetened beverage consumption categories were relatively equal (none 32.0%, one or less 31.0%, and one or more 36.1%), and stratifying the model for this age group yielded AOR 3.0 (95% CI 1.5-6.0) for less than one daily and AOR 4.1 (95% CI 2.1-8.0) for one or more daily versus none for sugar-sweetened beverage consumption as a predictor for bedbug infestation.

Commented [LT27]: From LORNA: I could not follow this. I see you are trying to establish a dose-response, which I applaud. I am suspect, however that there is such a big OR for less than one daily compared to none. Why did you restrict this to 25-44 year olds? If you do keep this, I suggest you make it a separate paragraph and be explicit that this was done in a separate analysis (not in the model).

From HEIDI: Perhaps you should make it clearer that age was highly associated with drinking sugar drinks in the younger and older age groups, so you restricted the analysis to the middle age group that had more variability.

Potential Health Outcomes of Bedbug Infestation

Only NSPD, and diagnosed depression had significant associations with bedbugs in unadjusted models, but neither of these associations was significant in the final adjusted models (Table 3). Asthma as an outcome did not appear to be associated with bedbug infestation (OR 0.9, 95% CI 0.6-1.5), nor did emergency visit for asthma in the past 12 months (OR 1.5, 95% CI, 0.6-4.3), although only 33 cases reported an emergency visit for asthma.

Discussion

This analysis is one of the first population-based studies to estimate reported bedbug infestation prevalence in an urban setting and to evaluate predictors associated with infestation. Our examination includes individual, household and environmental predictors, and provides a benchmark for future research on urban bedbug infestations. Risk factor data may be useful for preliminary testing of transmission theories and for comparison to other kinds of insect infestations to help us understand the dynamics and possible consequences of a changing entomological landscape.

Commented [LT29]: Stylistic comment: I prefer the first paragraph of a paper to give the main heading of what interesting findings you identified, and I would comment on the usefulness of this paper as a benchmark, etc in the final paragraphs, not right away. First I want to assure the reader knows what knowledge I am contributing before I say how important it is.

I think you could append the below paragraph to your first sentence and let this be paragraph 1.

Overall, we estimated that nearly one in fifteen NYC households reported a bedbug infestation in the past year in 2009, with a citywide prevalence of 6.7% and significant differentiation across the city's boroughs. In the adjusted model, factors associated with infestation included household and neighborhood poverty, echoing literature on risks of other insect infestations.[25] The number of units in the building was also a strong predictor. Adjusting for poverty (graded associations which remain robust) attenuated all individual respondent-level associations to insignificance with the exception of younger age. Other than household poverty level, total household size was the only other household level significant predictor. In adjusted models, bedbug infestations showed no significant association with any health or mental health outcome.

While reasons for some of the observed associations are not known, we can conjecture on potential mechanisms or potential biases that may account for our findings. At the individual

Commented [LT30]: From LORNA: I think you need some overarching statement that acknowledges that what you are about to conjecture upon is just that.

From HEIDI: I agree , generally a good idea to separate out conjecture/speculation from data driven by your study findings in the discussion

respondent level, aAge may be marker for social behaviors that increase bedbug hitchhiking, including …. Higher likelihood of reported infestation for younger ages may be measuring a range of cohort specific infestation risk associated with environmental, health, behavioral or cultural characteristics such as different housing, different diet, more travel or higher social contact. We should note, however, that associations with individual characteristics may also reflect dynamics of higher levels of reporting, rather than infestations, for example, younger age groups with greater media susceptibility, higher skin sensitivity, or differences in perception of stigma.

Behaviors or conditions within different households – e.g., crowding, children in daycare or schools, members frequenting community centers, collecting clutter – may also affect risk for bedbug infestation, and may complicate reporting by raising risks of other household pests. At the household level, the association with larger families, may indicate more aggregate social exposure and subsequent higher risk of introduction through hitchhiking.

Links to neighborhood poverty may be due to poor housing stock, greater crowding, or aggregation of other individual risks not accounted for in the model. In addition, once prevalence is elevated in a community, individual risks per social transaction may be elevated due to the higher background prevalence itself, thus perpetuating risks in these settings. Infestation levels may be related to less effective building management, which may be determined by the resources and recourse of tenants.[27] If points of egress (pipes or conduit)

Commented [LT31]: Not specific enough to be useful.

Suggest adding the borderline sex behavior results here too.

Commented [LT32]: From LORNA: Suggest deleting this first sentence too. Also unclear – Making too many jumps for the reader, and leaps too far in conjecture.

Try systematically addressing each of your findings in a more systematic way.

I would have 1 paragraph about the individual level findings, then one about

Commented [LT33]: From LORNA: I think you need to list all plausible reasons, not just poor housing stock. I wasn't very clear in my choice of text here but see if you find these suggestions helpful to work on.

between apartments above, below, or adjacent have not been sealed, bedbugs may be encouraged to travel within the building and between apartments. This transmission mechanism -- in larger buildings, and in poor housing stock in particular -- is supported here by the lower levels of infestation in 1-2 unit buildings. In these smaller buildings, introduction must come from outside or from only one adjacent apartment, which in turn would have introduction only from the outside. Apartments in larger buildings may also be more often subject to transfer from common areas, or from other building features that depend on unit count, increasing transmission risks for all apartments through within-building transmission. Regardless of common areas or building management, building characteristics associated with larger apartments may create some unseen risk factors for transmission, such as vertical adjacency to more rooms and apartments.Although unit count may correlate with a number of other risk factors such as income, household size and neighborhood and could thus reflect residual confounding, further examination of bedbug infestation by building type may identify structural risks and offer guidance in resource allocation for pest control.

[This paragraph feels incorrectly placed – should be in the health outcomes section. First you NEED to acknowledge the good news of no observed association with examined health outcomes before trying to raise alarm about something you did not look at.] These findings highlight other potential health issues that may result from infestation. Low-income tenants especially may not have control over extermination techniques, and may not have access to best management practices such as low-toxicity bedbug management. In low-income housing

where higher risk of other types of infestation already exist, new increased risk for bedbugs may augment the current disproportionate burden for low-income populations, particularly if there is a subsequent new higher risk of pesticide exposure. Families with children under six, while not at special risk, have a high burden in this sample, and young children are vulnerable to a vastly greater health impact from pesticide use. This group should come under special consideration as resources are allocated.

Our exploration of sugar-sweetened beverages deserves mentioning. The impact of sugar-sweetened beverage consumption on the 25-44 age range may be indirectly measuring social and behavioral differences; one could easily see, for instance, susceptibility to soda marketing as a correlate to susceptibility to influence of media in the reporting of bedbugs as an epidemic, which could lead to greater reporting. Nevertheless, it is worth noting that there is biological plausibility for the impact of sugar consumption on reporting and infestation levels.

Commented [LT34]: I suggest you have one paragraph on SSB only – shorten and combine.

In the existing research literature, there are indicators that diet, particularly sugar consumption, could plausibly have an effect on bite sensitivity and dermatological presentations. Sugar, carbohydrates and alcohol may have a complex connection to allergic reaction and inflammatory response, and may affect dermatological presentation.[28-30] Bedbugs seem to be attracted to carbon dioxide (CO_2),[31] which may increase in the exhaled breath of humans with high sugar consumption.[32] Further, sugar in blood meals have been associated with increased fecundity in a range of insects,[33] and could plausibly increase the

severity of infestation and speed of transmission within subgroups. Sugar-sweetened beverage consumption turned out to be surprisingly robust in the final bedbug infestation model. These findings warrant further investigation of potential links to inflammatory response and subsequent higher reporting, and of other biological factors that could account for higher infestations levels, such as an increased CO2 production after consumption or stimulated bedbug fertility with high-sugar blood meals.

Health and Mental Health Outcomes

Commented [LT35]: From LORNA: Suggest you don't use headers in Discussion. Not common, but depends on your target journal.

Bedbug infestation was not significantly associated with any health and mental health outcomes examined It is of particular interest that, unlike cockroaches[34], bedbugs showed no association with the asthma or asthma-related emergency department visits outcome. This may be due to limited study power to detect a small effect, fewer or different allergens for bedbugs, more prompt and definitive extermination from a higher perceived nuisance factor, or a number of pest control practice differences for bedbugs compared with other household pests, but there is little reason to assume there was an association to confound. In short, our findings do not support the suggestion in one study of possible associations found in a small sample [15].

Commented [LT36]: From LORNA: What does this mean?

Limitations

Commented [LT37]: Suggest no headers and should be in past tense.

This study is cross-sectional, which limits conclusions about temporal order. The primary outcome variable is reported infestations *in the past year*, however, and many covariates, such as education, poverty and children ages 13-17, likely predate infestation. Especially important

for health and mental health outcomes, infestations "in the past year" may represent ongoing infestations, and responses may miss those infestations that predate or were coincidental with health and mental health outcomes modeled here. Links to some health consequences may be more long-term than is possible to measure in this analysis: mental health outcomes may be latent; and any disease associated with pesticide use may depend both on the stage of cumulative exposure and on the latency for the disease in question. It is unlikely that this kind of delayed association could be measured against such a recent rise in infestations, or rise in bedbug-related exterminations. Other events, such as neighborhood media coverage of bedbug epidemics, may temporarily influence bedbug identification.[35]

Bite sensitivity may influence bedbug reporting, and population sensitivity prevalence is largely unknown.[36] Among those who react to bites, dermatological presentation varies, and may be delayed, making clinical diagnosis difficult. Sensitivity may increase with exposure, and, as a consequence, may change reporting in this population going forward. Bedbugs are small, hide during the day and have different appearance at different life stages, which may lead to resident misidentification, as is anecdotally reported by exterminators, and misidentification may be differential within a given population.[37]

Other factors may obscure true infestation prevalence, with potential negative reporting in subgroups due to stigma or increased or decreased reporting from pressing health concerns. For instance, parents may be more attuned to possible infestations than adults without

children. This survey asked about bedbug infestations which required an exterminator, and caution should be used in interpreting this prevalence as the level of infestation. An individual or building manager calling an exterminator could have a range of determinants yet to be quantified, such as cost as discussed above or nuisance. Some groups, such as immigrants from areas where bedbugs have a more recent history, may have experience managing bedbugs on their own, and others, such as asthmatics, may have lower tolerance for perceived risk or presence of infestation and exterminate prophylactically. Our findings on prevalence across demographic factors may help correlate infestations with other data sources, such NYC levels of complaints and building violations, as a preliminary step in establishing proxies for infestation.

Commented [LT38]: I suggest simplifying this section - - a little too detailed in conjecture.

In spite of the issues surrounding infestation self-report, psychological outcomes may not depend on correctly identifying infestations; in fact, the impact of the bedbug resurgence may best be described by self-report. Just as media may contribute to the population reporting, the stress conveyed on the population by increased level of infestations may have an impact distribution different from the aggregate of individuals experiencing actual bedbug infestations. It is also possible that self-report will prove to be an accurate marker of infestation levels as more information becomes available.

Lastly, NYC has a distinct and diverse profile, with a unique demographic makeup overall, and unusual concentrations of specific populations. Population density, immigration, relative financial stress and extermination costs may all have an impact on bedbug transmission,

reporting, and subsequent health outcomes. Local laws, state and local programs, and public education practice may affect prevalence and distribution (via introduction and transmission) of infestations and extermination. As relates to public health, other mental health outcomes, such as anxiety disorders not addressed by the NSPD survey questions, or delusional infestations, may be more closely associated with reported bedbug infestations, and the findings for the specific conditions analyzed should not be overgeneralized.

Commented [LT39]: True – but a bit too broad and vague. Make a key point, and focus on key points. Don't try to cover everything in single sentences.

Conclusions

Commented [LT40]: Good. If you are going to keep any hader – this might be the most useful.

Poverty-related factors seem to drive much of the differentiated prevalence in this sample. The cost of extermination may be a barrier to effective pest control in the population most at risk, and higher levels of infestation may exacerbate economic or health disparities. If not addressed thoroughly and systematically, disadvantaged residents and neighborhoods could create a reservoir of bedbug populations. Transmission mechanics may be multifactorial. Environmental risk factors suggest building level issues be investigated for interventions, and risk for younger ages and household size may reflect social contact and suggest community interventions as well as public education models. Determining differentials of reporting in future research may help rule out bite sensitivity as a confounder of infestation distribution and open the door to use of instrumental variables to measure bedbug prevalence. The association of bedbugs with consumption of sugar-sweetened beverages may be due to residual confounding by income or other factors, but the strength and robustness of the association and the biological plausibility of influence of dermatological presentation, bedbug attraction or bedbug fertility after feeding differentiation is speculative but may warrant further investigation.

– Congratulations on a beautifully done paper. We have awarded you an "A" (total points: 96) on the basis of your thorough analysis, careful thinking about the problem, and quality of the write up. Our comments were all addressed, and your responses to us in the letter were appropriate. We encourage you to seek publication!

On this draft, I mainly provide critique on sections still needing a little work and try to point out strong sections. We can discuss possible track change suggestions later if you prefer. Congratulations again!

Self-reported bedbug infestation among New York City residents: prevalence and risk factors, 2009

Author:

Target Journal: Journal of Urban Health

Abstract length: 224 Words

Essay length: 3,878

Abstract

Introduction

Since 2004, bedbug infestations have risen precipitously in urban areas. Although bedbugs have not been shown to transmit disease, bites may cause dermatological reactions and mental stress. Little is known about overall prevalence of and risk factors for infestations.

Methods

In the 2009 Community Health Survey of New York City (NYC), an annual cross-sectional, representative study of non-institutionalized adults, 9,934 participants reported on bedbug infestation requiring an exterminator in the past year. We used logistic regression to model infestation with demographic, behavioral and environmental factors, and to model health outcomes with bedbugs as a predictor adjusting for possible confounders.

Results

In 2009, 6.7% of individuals reported bedbug infestations. In a multivariable model, bedbug infestations were associated with age (18-24 and 25-44 vs. 65+ Adjusted Odds Ratio [AOR] 2.0, 95% Confidence Interval [CI], 1.4-2.9 and AOR 1.8, 95% CI 1.1-2.9, respectively), poverty (<200% Federal Poverty Level [FPL] vs. >=200% FPL, AOR 2.7, 95% CI 1.9-3.9), 3+ adults in household vs. 1 (AOR 1.6, 95% CI 1.1-2.4), and neighborhoods with highest poverty tertile vs. lowest (AOR

1.9, 95% CI 1.1-3.1). Living in buildings with <2 units vs. 50+ units was protective. Diabetes, asthma and depression were not associated with reported infestations.

Conclusions

Differences by individual, household, building and neighborhood characteristics support both bedbug hitchhiking and apartment-to-apartment travel. Exactly why risk is elevated among younger adults, low-income households and low-income communities is not well characterized.

Commented [LET1]: Readers will probably be surprised to see you examining diabetes as a health outcome. Not clear why (whereas asthma and depression are more logical).

Commented [LET2]: This "wrap-up" still needs work. The hitchhiking vs apt-to apt travel assessment wasn't set up in the background, and results don't clearly demonstrate this without explanation. I don't think you'll be able to present this concept in the abstract successfully.

Introduction

Bedbug infestations, once a common problem worldwide, virtually disappeared in the industrialized world after World War II. In the past 5-10 years, however, reports of bedbug infestations in urban centers have risen precipitously, with many urban areas around the world reporting double-digit increases.[1, 2] The prevalence of bedbugs appears to be widely divergent in the United States (U.S.),[3] although investigations have largely used complaints to estimate burden on a population basis. Bedbug complaints to New York City's (NYC) 311 telephone line began increasing sharply in the past decade, from 537 in 2003 to 1,839 in 2004, following a steep gradient to 10,985 in 2009.[4]

Commented [LET3]: Is your point here that the divergent prevalence estimates may be in part due to reliance on imperfect administrative data, such as complaints? Then maybe it is helpful to say that a little more directly...Right now the paragraph talks about increases, then imperfect data, then increases again. Might this flow a little more clearly if your last sentence was moved up to be before the sentence about divergent experiences?

Little is known about risk factors for bedbug infestation. Bedbug transmission has largely been assumed to happen via "hitchhiking" – the ability of bedbugs to sequester themselves on clothing or personal items, which are then moved by their owners to new locations. Human transfer may occur while visiting infested places outside the home, or residents may unwittingly introduce bedbugs into their homes by acquiring infested furniture, clothing or toys.[5] Historically, research has suggested that building characteristics may present higher risk; low-income households may have greater risk of other pest infestations (such as mice or cockroaches) due to overcrowding, poor housing stock, and implied housing management issues.[6] More recently, field reports from one study proposed apartment-to-apartment bedbug travel via structural egress points such as hallways or electrical conduit.[5]

Commented [LET4]: Para 2-4 are all excellent!!

The physical health impact of the apparent rise in infestations has yet to be determined. Known health effects of bedbugs are primarily limited to rare cases of anaphylactic shock,[7, 8] and dermatological bite reactions of blisters and rashes.[9, 10]. Bites can itch, which may lead to secondary infection from scratching.[11] Unlike cockroach allergens,[12] no association between bedbug infestation and asthma onset or exacerbations has been found,[13] although research has been limited. Bedbugs have also proven to be unlikely transmitters of most infectious diseases, probably through a combination of minimal blood transfer during feeding and barriers to viral replication within the insect itself.[14-16] Possible exceptions are Hepatitis B,[11] and the recent hypothesis that bedbugs could serve as a reservoir for Methicillin-resistant Staphylococcus aureus (MRSA).[17] To date, dermatological presentations and vector competency for transmitting infectious diseases have dominated research on health outcomes caused by bedbugs.

Bedbug infestations may cause mental stress. One study found that among 474 households with confirmed cases of bedbugs, residents reported experiencing mental health symptoms in relation to infestations, including: sleeplessness (29%), anxiety (20%), emotional distress (22%) and stress (14%).[18] Cases of delusional parasitosis have been reported both as a purely psycho-social phenomenon and an immediate aftershock of cleared infestation.[19] Bedbug related skin conditions may add to mental stress.[9, 10] Anecdotes of social ostracism – from job loss to dating barriers – have been noted in social networking outlets and other media.[20-22]

In this study, we used self-reported data from a community-based municipal telephone survey conducted by New York's Department of Health and Mental Hygiene (NYC DOHMH) in 2009 to estimate the prevalence and distribution of bedbug infestation in New York City. To explore and understand risk factors we used these data to examine demographic and behavioral characteristics, household composition and building and neighborhood environmental characteristics as possible determinants of infestation. This analysis will add to the knowledge of individual, building and neighborhood-level determinants to help generalize these findings and quantify risks. We also examined health and mental health characteristics as possible outcomes of infestation.

Commented [LET5]: Might adding to the knowlege help guide prevention and control programs?

Methods

Data Source

The Community Health Survey (CHS) is an annual representative cross-sectional telephone survey of NYC adults aged 18 and older. This survey is administered by the NYC DOHMH and collects self-reported measures of health, behaviors and demographic characteristics using a neighborhood stratified random sample. Details of the study and sampling scheme are reported elsewhere.[23]

In 2009, the CHS had approximately 125 questions. Responses were collected using a computer assisted telephone interview format. Interviews were conducted in English, Spanish, Russian or Chinese. Group residences, such as college dormitories, and homes of families with both

landlines and cell phones were excluded. Among households agreeing to participate, one adult was selected at random to complete the survey, which took an average of 25 minutes to complete. The response rate was 34% for landline and 50% for cell phone, with a cooperation rate of 88% and 97%, respectively. The survey and method for gathering informed consent was approved by the DOHMH Institutional Review Board. The current analysis was deemed exempt from review by the CUNY Hunter College Institutional Review Board.

Measures

We used CHS responses to generate prevalence estimates, explore predictors of self-reported bedbug infestation, and examine the extent to which bedbug infestation predicted key health outcomes. Bedbug infestation was measured as a dichotomous response to: "During the past 12 months, have you had a problem with bedbugs in your home that required an exterminator?"

Individual predictors of bedbug infestation explored were all self-reported, and included age (grouped 18-24, 25-44, 45-64, 65+ years), sex, race/ethnicity (white, black, Asian, Hispanic; "other" [n=175] was recoded as missing), education (less than high school, high school graduate, some college/technical school, college graduate), household poverty status (<200% of Federal Poverty Level [FPL] vs. >=200% of FPL), partnership status (married/member of unmarried couple vs. divorced/widowed/separated/never married) and country of nativity (U.S. vs. foreign born). For behaviors, we explored number of sex partners (0-1 vs. 2 or more). Environmental predictors included neighborhood poverty levels (high, medium, low – based on

tertiles of percent of residents living with incomes <200% FPL), and number of units in building (1-2 units, 3-9 units, 10-49 units and 50 or more units).

As an exploratory measure, we also examined sugar sweetened beverage consumption (average consumed per day; none, less than one, one or more). In the existing research literature there are indicators that diet, particularly sugar consumption, could plausibly have an effect on bite sensitivity. Sugar may have a complex connection to allergic reaction and inflammatory response, and may affect dermatological presentation.[24-26] Bedbugs also seem to be attracted to carbon dioxide (CO2),[27] which may be higher in the exhaled breath of humans with high sugar consumption.[28] Further, sugar in blood meals have been associated with increased fecundity in a range of insects,[29] and could plausibly increase the severity of infestation and speed of transmission.

In separate analyses, health outcomes and coping mechanisms examined included current depression, first diagnosis of depression in last 12 months, non-specific psychological distress (NSPD), ever diagnosed with diabetes, ever diagnosed with asthma, and asthma-related emergency department visits in the past 12 months, heavy alcohol drinking, binge drinking. NSPD, described by Ridner as having five defining attributions of harmful psychological impairment,[30] as have been was determined by the standardized K6 scale, a standardized six-question short screening for mental health.[31] Diabetes, asthma and depression were determined by dichotomous answers to standardized questions modeled after the Behavioral

Commented [LET6]: To me, the rationale for examining diabetes is insufficiently clear. You might consider taking it out of the next version.

Risk Factor Surveillance System for self-report of diagnosis by a health professional. ("Have you ever been told by a doctor, nurse or other health professional that you had [*condition x*]?"). Heavy alcohol drinking was defined as >2/day for men, >1/day for women, and binge drinking was defined as reporting five or more drinks on at least one occasion in the past 30 days. In models exploring the association between bedbug infestation and select health outcomes, we also examined insurance status (private, Medicare, Medicaid/Family Health Plus, other, uninsured) as a possible confounder of health outcomes through differentiated likelihood of diagnosis.

Data Analysis

Analyses in this study were performed using SAS version 9.2 (SAS Institute, Cary, NC). DOHMH-developed weighting strategies were applied to adjust for sampling methodology, adult telephone usage,[32, 33] and to reflect age, gender and race distributions of neighborhoods (zipcode aggregations designated by the United Hospitalization Fund). To identify factors associated with bedbug infestation, each covariate was analyzed in bivariate logistic regression using a chi-squared test. Those with significant p-values at the 95% confidence level were included in a final multivariable logistic regression model with reported bedbug infestation as the outcome. In order to adjust for household size (significant in unadjusted models) and age of children, we included number of children by age group (<6 years old, 6-12 years old, 13-17 years old), and number of adults aged 18 and older (recoded to 1, 2, and 3 or more) in the adjusted bedbug model, regardless of unadjusted significance.

Commented [LET7]: FYI only: Typically this is cited.

Commented [LET8]: From what I gather, your aim is to examine both household size and age of children as potential predictors of bedbug infestation, correct? If so, consider modifying beginning of sentence to make that clear (not just adjusting for them as nuisance variables)

To characterize potential health effects from bedbug infestation, we created separate models for each of the health outcomes examined. Base models each had bedbugs as the only predictor. We then examined each covariate with significant association to bedbugs in a bivariate model with the outcome. Where a covariate association was significant, we added this factor to the base model. If the covariate effected a 10% change in the beta coefficient for bedbug infestation, we added the covariate to the final model, to adjust for possible confounding of the relationship between bedbug infestation and the health outcome of interest.

Results

In 2009, 6.7% (95% CI 5.9-7.5) of adults self-reported a bedbug infestation requiring an exterminator in the past year. (Table 1) By borough, Brooklyn had the highest level of infestation (8.9%) and Staten Island the lowest (2.5%). The distribution of bedbug infestations showed an inverse relationship with age of the adult respondent, ranging from 10.5% for those 18-24 years old to 3.5% for those 65+. Hispanic residents had the greatest proportion of reported infestations (10.5%), the proportion among blacks was also elevated compared with whites (7.4%), and white residents had the lowest (3.8%, $p<0.01$). Those with low household poverty status (<= 200% of FPL) had significantly higher reported infestations compared with those with higher income (12.0% vs. 3.6%), and this negative association pattern was consistent with two other measure of socioeconomic status: education (12.4% less than high school through 4.5% for college graduate, $p<0.01$), and neighborhood poverty levels (10.9% for high poverty neighborhoods and 3.2% for low poverty neighborhoods, $p<0.01$).

Commented [LET9]: Odd terminology – low poverty status…. Perhaps lower income or greater poverty…?

Overall, there was a higher burden among respondents with children under 18 years of age, and we observed a positive gradient of association with total number of children (data not shown). When number of children was categorized by age, the gradient was most pronounced among younger ages. (Table 1) Likewise, number of adults in the household showed a positive gradient with infestations. Respondents reporting having no or one sexual partner appeared to have fewer infestations than those having two or more (6.7% versus 10.5%, p=0.01). The differences in infestations among those with any measures of asthma were not significant.

Commented [LET10]: If you have space in text, consider describing, because it feels a little hollow to be told there is a positive gradient assoc but not see it.

Commented [LET11]: I'm not clear why asthma is shown as a possible predictor of bedbug infestation – didn't anticipate this based on the Methods section I just read...

In the final adjusted model containing factors significant in bivariate analysis, only younger age of respondent (compared to 65+, 18-24 adjusted odds ratio [AOR] 2.0; 25-44 AOR 1.8), household poverty status below 200% of FPL compared to higher income (AOR 2.7), three or more adults compared with one (AOR 1.6), and highest tertile of neighborhood poverty compared with lowest tertile (AOR 1.9) were significant positive predictors of bedbug infestation. (Table 2) Education was excluded from consideration for the final model with bedbugs as the outcome, as any association between education and infestations disappeared when adjusted for poverty status. Living in a 1-2 units in building compared with 50 units or more was protective (AOR 0.4), compared to living in a building with 50 or more units. Associations of bedbug infestations with race and numbers of children in all age groups were no longer significant in the adjusted model.

The exploratory variable, sugar-sweetened beverages was significantly associated with bedbug infestation in both unadjusted and adjusted models (less than one beverage per day, AOR 1.8, 95% CI 1.2-2.6; and one or more per day, AOR 2.0, 95% CI 1.4-3.0 compared to none). Adding the consumption of sugar-sweetened beverages to the adjusted model, improved the model fit and attenuated the association between age and bedbug infestation (data not shown).

Prevalence of select coping mechanisms, health and mental health outcomes were as follows: current depression, 13.1% (95% CI 12.1-14.1), first diagnosis of depression in last 12 months, 3.9% (95% CI 3.4-4.5), NSPD 5.0% (95% CI 4.4-5.7), heavy alcohol drinking 4.8% (95% CI 4.1-5.5), binge drinking 15.0% (95% CI 13.8-16.2), ever diagnosed with asthma 11.3% (95% CI 10.3-12.3), episode of asthma in the past 12 months 4.1% (95% CI 3.4-4.6), and asthma-related emergency department visits in the past 12 months, 2.0% (95% CI 1.6-2.3), and diabetes (ever) 9.2% (95% CI 8.5-10.0). Only NSPD and diagnosed depression had significant associations with bedbugs in unadjusted models. Neither of these associations was significant in the final adjusted models. (Table 3) Asthma as an outcome did not appear to be associated with bedbug infestation (OR 0.9, 95% CI 0.6-1.5), nor did emergency visit for asthma in the past 12 months (OR 1.5, 95% CI, 0.6-4.3), although only 33 households with bedbug infestations reported an emergency visit for asthma.

Commented [LET12]: Odd: I don't see diabetes described here. Did you look at it?

Discussion

This analysis is one of the first population-based studies to estimate the prevalence of reported bedbug infestation and associated predictors in an urban setting. Overall, we estimated that nearly one in fifteen NYC households (6.7%) reported a bedbug infestation in the past year in 2009, with significant differentiation across the City's boroughs. In the adjusted model, the only demographic factor associated with infestation was age. At the household level, factors associated with infestation included household poverty and number of adults, echoing literature on risks of other insect infestations.[6] Significant building- and neighborhood-level factors included neighborhood poverty and number of units in the building. These findings may be useful for guiding prevention and infestation control measures, as well as estimating the impact of various transmission mechanisms. By comparing these patterns to other kinds of insect infestations, we may also better understand the dynamics and possible consequences of a changing entomological landscape.

Commented [LET13]: Consider fleshing this sentence out to summarize the direction of association.

The exact role of these identified individual, household and environmental factors in bedbug transmission are unknown; some possibilities are discussed below based on the two most likely means of bedbug transmission proposed in previous research: hitchhiking and apartment-to-apartment travel.[11] At the individual respondent level, age may be a marker for social behaviors that increase bedbug hitchhiking, such as more frequent and wider socialization, different use of transportation (public vs. private, bus vs. train, taxi vs. car), libraries, schools or other public spaces, more frequent exchange or collection of used furniture or clothing, more frequent local or international travel, more crowded apartments, or other cohort specific

behaviors that change the risk profile. We should note, however, that associations with individual characteristics may also reflect dynamics of an increased propensity to report infestations, rather than actual infestations themselves. For example, younger age groups could exhibit greater media susceptibility and as a consequence interpret any insect infestation as a bedbug infestation, they could have higher skin sensitivity and be more likely to perceive true infestation, or have a perception of stigma different from older age groups and be more likely to acknowledge infestation.

Our finding that more adults in the household increases infestation risk may be reflecting a greater aggregate social exposure and subsequent higher risk of introduction through hitchhiking. Because we have no way of assessing ages of other adults outside of respondents, we did not examine the impact of number of adults stratified by age group in the same way as we did for children. Having more adults may, in fact, be a sign of a greater mix of ages of adults in the household. As infestation risk may be the aggregate risk of household members, having a greater likelihood for higher risk (possibly younger) individuals may increase the risk across multi-adult households. In spite of the higher prevalence of infestation among households with more younger children, in the fully-adjusted model, we did not see that number of children in the household was associated with infestation. Household poverty could also increase the odds for hitchhiking, through similar acquisition of used clothing or property, or frequenting public services. The higher risk associated with neighborhood poverty may be reflecting hitchhiking transmission through a higher level of contact from high density housing and crowded

Commented [LET14]: Consider dropping or simplifying.

apartments, or through the same (or higher) contact with a population at higher risk through individual poverty levels.

These findings can also be interpreted to support the possibility of apartment-to-apartment transmission. The greater likelihood of infestation among higher poverty households may reflect the resources, recourse and self-efficacy of tenants to ensure effective building management.[34] Building size is also positively correlated with infestation risk, with lower levels of infestation in 1-2 unit buildings. If points of egress (pipes or conduit) between apartments above, below or adjacent have not been appropriately sealed, bedbugs may be encouraged to travel within the building and between apartments; in these smaller buildings, introduction must come from outside or from only one adjacent apartment, which in turn would have introduction only from the outside. Apartments in larger, and, particularly, poorly managed buildings may also be more often subject to transfer from common areas, such as lobbies or laundry rooms, or from other building features that depend on unit count. These entry points may also increase transmission risks building wide through apartment-to-apartment transmission in buildings with higher levels of infested apartments. Although unit count may be confounded by a number of other risk factors such as income, household size and neighborhood, further examination of bedbug infestation by building type may identify building-level risks and offer guidance for methods of pest control.

Commented [LET15]: Discussions on hitchiking and apt-to-apt travel are now excellent! A couple of minor comments only....Nice work!

Commented [LET16]: "Lack of...", or "reduced"

Bedbug infestation was not statistically significantly associated with any health and mental health outcomes examined. It is of particular interest that, unlike cockroaches,[35] bedbugs showed no association with the asthma or asthma-related emergency department visits outcome. This may be due to limited study power to detect a small effect, more prompt and extreme extermination efforts from a higher perceived nuisance factor, a number of pest control practice differences for bedbugs compared with other household pests, or fewer or different allergens for bedbugs, but there is little evidence to support the likelihood of an association being masked by confounding. In short, our findings do not support the prior suggestion of a possible association of bedbug infestation with asthma found in a study using a sample of 11 bedbug-infested households.[13]

Commented [LET17]: Good material in this sentence but a bit too dense. Consider breaking into two sentences.

Findings seen here do, however, highlight the possibility of other potential health issues that may result from this distribution of infestation. Low-income tenants especially may lack control over extermination options, and may not have access to best management practices such as low-toxicity bedbug extermination. In low-income housing where higher risk of other types of infestation already exist, the increased risk for bedbugs may augment the current disproportionate total burden of pesticide exposure for low-income populations. Families with children under six, while not at special risk for bedbug infestation according to our data, did report a high prevalence of infestation, and young children are vulnerable to substantially greater health risks from pesticide use.[36, 37] This group should come under special consideration as education and pest control resources are allocated.

Commented [LET18]: Consider being clear that your study points to suggestions for other plausible health risks that should be examined in future studies...

Our exploration of sugar-sweetened beverages deserves mentioning. The impact of sugar-sweetened beverage consumption may be indirectly measuring other social and behavioral differences; for instance, susceptibility to soda marketing may correlate with susceptibility to influence of media in the reporting of bedbugs as an epidemic, which could lead to greater reporting. The observed association may also be due to residual confounding by income or other factors. Likewise, results could reflect residual confounding. Nevertheless, biological plausibility for potential links of sugar consumption to higher reporting or higher infestation levels warrant further study of this phenomenon.

Commented [LET19]: This sentence seems unnecessary and by repeating this sentiment, it seems confusing.

This study was cross-sectional, which limits conclusions about temporal order. The primary outcome variable was reported infestations *in the past year*, however, and many covariates, such as education, poverty and children ages 13-17, likely predate infestation. Especially important for health and mental health as outcomes, infestations "in the past year" may represent ongoing infestations, and responses to the question of infestation may have missed those infestations that predate or were coincidental with health and mental health outcomes modeled here. Hence, the effect of these earlier or persistent bedbug infestations may be underestimated for mental health outcomes. Links to some health consequences may require more time than is covered in this analysis: mental health outcomes may be latent for a period after first experiencing an infestation, and increased risk for any disease associated with pesticide use may depend both on cumulative exposure and time. It is unlikely that these kinds

of delayed associations could be measured against such a recent measure of infestations or exterminations. Other events, such as neighborhood media coverage of bedbug epidemics, may temporarily influence bedbug identification.[3]

Other factors may obscure true infestation prevalence, with potential negative reporting in subgroups due to stigma or increased or decreased reporting from pressing health concerns. For instance, parents may be more attuned to possible infestations than adults without children. Bite sensitivity may also influence bedbug reporting, and population sensitivity prevalence is largely unknown.[38] Sensitivity may increase with exposure, and, as a consequence, may change reporting, and prevalence estimates, going forward. Also, bedbugs are small, hide during the day and have different appearance at different life stages, which may lead to resident misidentification, as is anecdotally reported by exterminators, and misidentification may be differential within a given population.[39] This survey asked about bedbug infestations which required an exterminator, and caution should be used in interpreting this prevalence as the level of infestation – factors such as cost, experience, and cultural norms and overall health may have an impact on the pest control services used.

In spite of the issues surrounding the uniformity and accuracy of infestation, self-report may still be the best measure of the impact of the bedbug resurgence. Because of differences in bite sensitivity and in perception of threat, the psychological impact of the rise in bedbug infestations may be distinct from the experience of actual bedbug infestations; some

Commented [LET20]: This paragraph is good, but it could use some tighter synthesis to get points across more succintly.

individuals experiencing true infestations may have less awareness or experience less anxiety or stress from bedbugs than others who are not infested, but who are fearful of infestation. It is also possible that self-report will, as more information becomes available, prove to be an accurate marker of infestation levels. Even considering possible reporting biases in this study, our findings on prevalence across demographic factors may help evaluate and interpret measures of infestations from other data sources, such NYC levels of complaints and building violations, as a preliminary step in establishing proxies for infestation.

Lastly, NYC's population and housing stock is unique, diverse, and subject to local environmental characteristics and municipal policies that may have an impact on bedbug transmission and limit generalizability.

Commented [LET21]: Might be more effective to avoid using "unique" and try and pinpoint what specific characteristics are unique and relevant to this research question.

Conclusions

Individual and environmental poverty-related factors seem to drive much of the differentiated prevalence in this sample and cost of extermination may be a barrier to effective pest control in this population. If not addressed thoroughly and systematically, those living in disadvantaged neighborhoods could be exposed to a greater reservoir of bedbugs, possibly furthering the high risk in an already-burdened population and making neighborhood control more difficult. Multiple transmission mechanics may be at work. Environmental risk factors suggest that building-level issues can be investigated for interventions, and risk for younger ages and household size suggest community interventions as well as public education models. Determining differentials of reporting in future research may help rule out bite sensitivity as a

Commented [LET22]: Rethink this sentence – Did you actually show that these risk factors explained much of the variance? How do you know cost might be a barrier? By putting it in this particular sentence, it implies your findings show this. If sop, explain how.

Rest of paragraph is excellent!

confounder of infestation distribution and open the door to use of instrumental variables to measure bedbug prevalence. The association of bedbugs with consumption of sugar-sweetened beverages may be due to residual confounding by income or other factors, but the strength and robustness of the association and the biological plausibility of influence of dermatological presentation, bedbug attraction or bedbug fertility after feeding may warrant further investigation.

Self-Reported Bed Bug Infestation Among New York City Residents: Prevalence and Risk Factors

[redacted], MPH
Heidi E. Jones, MPH, PhD
Lorna E. Thorpe, MPH, PhD
CUNY School of Public Health at Hunter College

Abstract Bed bug infestations have risen precipitously in urban areas. Little is known about risk factors for infestations or health outcomes resulting from these infestations. In the 2009 Community Health Survey, which is a representative population-based survey, 9,934 noninstitutionalized adults in New York City reported on bed bug infestations requiring an exterminator in the past year. The authors estimated infestation prevalence and explored predictors of infestation and associations between infestations and health outcomes using logistic regression. Seven percent of adults in New York City reported bed bug infestations. Significant individual and household risk factors were younger age, increased household poverty, and having three or more adults in the household. Environmental risk factors included living in high poverty neighborhoods and in buildings with more housing units, suggesting apartment-to-apartment transmission. Bed bug infestations were not associated with stress-related outcomes of alcohol consumption or recent depression, and, unlike cockroach infestation, were not associated with recent asthma episodes caused by allergens or contaminants.

Introduction

Bed bug infestations virtually disappeared in industrialized countries after World War II. In the past decade, however, urban centers around the world have seen double-digit increases in reported infestations (Boase, 2008; Doggett & Russell, 2008). In the U.S., measurement of infestation across geographic areas has not been systematic; estimates are frequently generated from housing complaints and municipal control efforts. To date, New York City has reported higher infestation levels, with data from the city's telephone complaint line indicating a sharp increase in the past decade, from 537 in 2003 to 1,839 in 2004 to 10,985 in 2009 (Centers for Disease Control and Prevention [CDC], 2011). These reports are unverified and interpretation of estimates remains challenging.

Little is known about risk factors for bed bug infestation. Bed bug transmission has largely been assumed to happen via "hitchhiking"—when bed bugs separate themselves on clothing or personal items and travel with new hosts who have visited infested places or acquire infested furniture, clothing, or toys (Wang, Saltzmann, Chin, Bennett, & Gibb, 2010). Historically, research has suggested that building characteristics may present higher risk for other infestations; for example, low-income households are at greater risk for mice or cockroach infestations, possibly due to overcrowding and poor housing stock, with implied inferior building management (Rauh, Chew, & Garfinkel, 2002). More recently, field reports from one study proposed apartment-to-apartment bed bug travel via structural egress points such as hallways or electrical conduit (Wang et al., 2010).

The physical health impact of the apparent rise in infestations has yet to be determined. Known health effects of bed bugs are primarily limited to rare cases of anaphylactic shock (Goddard & deShazo, 2009; Parsons, 1955) and more common dermatological bite reactions of blisters and rashes (Mazzotti et al., 2003; Sansporgna et al., 2004). Bites can itch, which may lead to secondary infection from scratching (Delaunay et al., 2011). Unlike cockroach allergens (Wang, Abou El-Nour, & Bennett, 2008), the limited studies examining possible association between bed bug infestation and asthma onset or exacerbations are inconclusive (Abou Gamra, el Shayeb, Morsy, Hussein, & Shehata, 1991). Bed bugs are unlikely to transmit infectious diseases (Jupp, Purcell, Phillips, Shapiro, & Gerin, 1991; Vaughan & Azad, 1993; Webb et al., 1989). Hepatitis B is a possible exception (Delaunay et al., 2011) with a second recent hypothesis that bed bugs could serve as a reservoir for methicillin-resistant *Staphylococcus aureus* (Lowe & Romney, 2011). Since the bed bug resurgence, studies on prevalence of dermatological presentations and vector competency for transmitting infectious diseases have dominated research on health outcomes.

Bed bug infestations probably cause mental stress, with largely unknown consequences. One study found that among 474 households with confirmed cases of bed bugs, some resi-

dents reported mental health symptoms in relation to infestations, including sleeplessness (29%), anxiety (20%), emotional distress (22%), and stress (14%) (Pottier et al., 2010). Recent research findings interpreted Internet blog-reported consequences of bed bug infestation such as sleeplessness, hypervigilance, and nightmares as possible cases of posttraumatic stress disorder (Goddard & de Shazo, 2012). Cases of delusional parasitosis have been reported both as a purely psychosocial phenomenon and as an immediate aftershock of cleared infestation (Freeman, de Jong, & Albrecht, 2008). Bed bug–related skin conditions may add to mental stress (Mazzotti et al., 2003; Sampogna et al., 2004). Anecdotes of social ostracism—from job loss to dating barriers—have been noted in social networking outlets and other media (Feldman, 2011; Fiegre, 2010; United Press International, 2010).

In our study, we used self-reported data from a community-based municipal survey conducted by New York City's Department of Health and Mental Hygiene (DOHMH) in 2009 to estimate the prevalence and distribution of bed bug infestation in New York City. We used these data to explore possible determinants of infestation, including demographic and behavioral characteristics, household composition, and environmental characteristics. We also examined health and mental health characteristics as possible outcomes of infestation.

Methods

Data Source

The Community Health Survey is an annual representative cross-sectional telephone survey of New York City adults aged 18 and older. This survey is administered by DOHMH and collects self-reported measures of health, behaviors, and demographic characteristics using a neighborhood-stratified random sample. Details of the study and sampling scheme are reported elsewhere (Mostashari, Kerker, Hajat, Miller, & Frieden, 2005). Briefly, in 2009, responses to 125 questions were collected using a computer-assisted telephone interview format available in English, Spanish, Russian, or Chinese. Group residences, such as college dormitories, were excluded. Among households agreeing to participate, one adult was selected at random to complete the survey. The response rate was 34% for landline phones with a cooperation rate of 88%, and 50% for cell phones with a cooperation rate of 97%. This study was approved by the DOHMH institutional review board; the current analysis was considered exempt by the Hunter institutional review board.

Measures

We estimated prevalence, explored predictors of self-reported bed bug infestation, and examined whether bed bug infestation predicts key health outcomes. Bed bug infestation was measured as a dichotomous response to the question, "During the past 12 months, have you had a problem with bed bugs in your home that required an extermination?"

Individual predictors of bed bug infestation included age (grouped as 18–24, 25–44, 45–64, or 65+ years), sex, race/ethnicity (Caucasian, African-American, Asian, or Hispanic; "other" [$n = 175$] was recoded as missing), education (less than high school, high school graduate, some college/technical school, or college graduate), household poverty status (<200% of federal poverty level [FPL] vs. ≥200% of FPL), partnership status (married/member of unmarried couple vs. divorced/widowed/separated/never married), and country of nativity (U.S. vs. foreign born). For behaviors, we explored number of sex partners in the past year (0–1 vs. 2 or more); as more sex partners could hypothetically be associated with greater exposure to bed bugs. Environmental predictors include neighborhood poverty levels (high, medium, low—based on tertiles of percentage of residents living with incomes <200% FPL), and number of units in building (1–2 units, 3–9 units, 10–49 units, and 50 or more units, by self-report).

In separate analyses, we examined the following health outcomes and coping mechanisms: first diagnosis of depression in last 12 months or nonspecific psychological distress (NSPD) to examine stress-related mental health issues; asthma episode in past 12 months or asthma-related emergency department visits in the past 12 months to explore possible effects of allergens or contaminants; and heavy alcohol drinking and binge drinking to investigate stress-related health impact. NSPD, described by Ridner as having five defining attributions of harmful psychological impairment (Ridner, 2004) was determined by the Kessler-6 scale, a standardized six-question short screening for mental health (Kessler et al., 2002). Heavy alcohol drinking was defined as >2/day for men and >1/day for women on days where the respondent drank, and binge drinking was defined as reporting five or more drinks on at least one occasion in the past 30 days (CDC, 2009). In models for select health outcomes, we included insurance status as a possible confounder due to the potential influence of differential likelihoods of diagnosis.

Data Analysis

We used SAS v. 9.2 for analysis. DOHMH-developed weights were applied to adjust for sampling methodology, adult telephone usage (Jacobs et al., 2010; New York City Department of Health and Mental Hygiene, 2010) and to reflect age, gender, and race distributions of neighborhoods. To identify factors associated with bed bug infestation, each covariate was analyzed in bivariate logistic regression using a Chi squared test; those with significant p-values of .05 or less were included in a final multivariable model. We quantified number of children by age group (<6 years old, 6–12 years old, or 13–17 years old), and number of adults aged 18 and older (recoded to 1, 2, and 3 or more) and included these measures in the adjusted bed bug model, regardless of bivariate significance, to examine infestation distribution by age.

To measure potential health effects of bed bug infestation, we created separate models for each health outcome. We selected potential confounders from significant variables in bivariate models with bed bugs as the outcome and, in a base model with bed bugs as the only predictor, we added each factor to the base model. If the covariate effected a 10% change in the beta coefficient for bed bug infestation, we added the covariate to the final adjusted model.

Results

In 2009, 6.7% of adults self-reported a bed bug infestation requiring an extermination in the past year, with prevalence varying by borough (Table 1). Overall, the distribution showed a clearly graded, inverse relationship with age, ranging from 10.5% for those 18–24 years old to 3.5% for those 65+. Hispanic residents had the greatest prevalence (10.5%) followed by African-Americans (7.4%) ($p < .01$) compared to Caucasians (3.8%). Those

with low household income (≤200% of FPL) had significantly higher reported infestations compared with those with higher income (12.0% vs. 3.6%). This pattern was consistent with two other measures of socioeconomic status: education (12.4% for less than high school through 4.5% for college graduate, $p < .01$) and neighborhood poverty levels (10.9% for high poverty neighborhoods and 3.2% for low poverty neighborhoods, $p < .01$).

A higher burden occurred among respondents with any children under 18 years of age, and we observed a positive gradient of association with total number of children (data not shown). When number of children was categorized by age, the gradient by number of children for infestation was most pronounced for households with children of younger ages (Table 1). Likewise, number of adults in the household showed a positive gradient with infestations. Respondents reporting having no or one sexual partner in the past year reported fewer infestations than those having two or more (6.2% vs. 10.5%, $p = .01$).

In the adjusted model, only younger age of the respondent (18–24 compared to 65+, adjusted odds ratio [aOR] = 2.0; and 25–44, aOR = 1.8), household poverty status below 200% of FPL compared to higher income (aOR = 2.7), three or more adults in the household compared with one (aOR = 1.6), and highest tertile of neighborhood poverty compared with lowest tertile (aOR = 1.9) were significant positive predictors of bed bug infestation (Table 2). Living in a 1–2 unit building was protective compared to living in a building with 50 or more units (aOR = 0.4). Associations of bed bug infestations with race and with number of children were not significant in the adjusted model.

Prevalence of health outcomes and coping mechanisms were: first diagnosis of depression in last 12 months, 3.9% (95% confidence interval [CI] = 3.4–4.5); NSPD, 5% (95% *CI* = 4.4–5.7); heavy alcohol drinking, 4.8% (95% *CI* = 4.1–5.5); binge drinking, 15% (95% *CI* = 13.8–16.2); episode of asthma in the past 12 months, 4.1% (95% *CI* = 3.4–4.6); and asthma-related emergency department visits in the past 12 months, 2.0% (95% *CI* = 1.6–2.3). Only NSPD was significantly associated with self-reported bed bug infestations in unadjusted models. This association was not significant, however, in adjusted models (Table 3). Emergency visit for asthma in the

past 12 months was not associated with bed bug infestation (OR = 1.5, 95% CI = 0.6–4.3), although only 33 households with bed bug infestations reported a recent emergency visit for asthma.

Discussion

This analysis is one of the first population-based studies to estimate the prevalence and associated predictors of reported bed bug infestation in an urban setting. In 2009, nearly one in 15 New York City households (6.7%) reported a bed bug infestation in the past year, with significant differences across the city's boroughs. In the adjusted model, the only individual-level factor associated with infestation was younger age, and at the household level, the only factors associated with infestation were household poverty and number of adult residents, echoing literature on other insect infestations (Rauh et al., 2002). Significant environmental factors included neighborhood poverty and number of units in the building.

The exact role of these factors in bed bug transmission is unknown. Possibilities proposed in previous literature are bed bug hitchhiking and apartment-to-apartment travel (Delaunay et al., 2011). Of these, hitchhiking is relevant to the broadest spectrum of the population. Age may be a marker for social behaviors that increase bed bug hitchhiking, such as differences in frequency and breadth of socialization; different use of transportation; different use of libraries, schools, or other public spaces; frequency of obtaining used furniture or clothing; and local or international travel.

Our finding that more adults in the household increase infestation risk may reflect a greater aggregate exposure or a greater likelihood of younger adults, with higher risk of introduction through hitchhiking. Because we do not know ages of other adults in the household we were unable to examine the impact of number of adults by age group. In spite of differential infestation prevalence by number of younger children, this was not associated with infestation in the fully adjusted model.

Household poverty could increase the risk of hitchhiking through acquisition of used clothing or property or frequenting public services. Neighborhood poverty may promote greater hitchhiking transmission through more social contact in high density housing. It may also reflect more frequent contact with a population at higher risk from poor building management, increasing building-to-building transmission in low-income neighborhoods.

These findings can also be interpreted to support apartment-to-apartment transmission: for household predictors, the greater likelihood of infestation among higher poverty households may reflect the lack of resources, recourse, and self-efficacy of tenants to ensure effective building management (Messer, 2011). We found that building size is positively correlated with infestation risk with lower levels of infestation in 1–2 unit buildings. If points of egress for bed bugs (door jambs, pipes, or conduit) between apartments above, below, or adjacent have not been appropriately sealed, more bed bugs may travel within the building and between apartments. In these smaller buildings, introduction must come from outside or from only one adjacent apartment; in larger buildings a greater potential exists for risk from adjacent units. Larger buildings may have more transfer from common areas, such as lobbies or laundry rooms, or from other building features associated with unit count. Although unit count may be confounded by risk factors such as income, household size, and neighborhood, further examination of bed bug infestation by building type may identify building-level risks and offer guidance for methods of pest control.

Bed bug infestation was not statistically significantly associated with any health or mental health outcomes examined. Unlike cockroaches, which are known asthma trig-

gers (Arruda et al., 2001), bed bugs showed no association with asthma exacerbation. Although factors such as limited study power to detect a small effect or different pest control strategies from a higher perceived nuisance factor may hide an asthma episode risk, little evidence exists to support the likelihood of an association being masked by behaviors or study limitations. Our findings from a representative population-based survey did not support the findings from a previous case series of 11 bed bug–infested households that suggested a possible association with asthma (Abou Gamra et al., 1991).

Our findings do suggest other potential health disparities that could result from this distribution of infestation. For example, in low-income housing, more infestations may augment the burden of pesticide exposure. While families with children under six were not at elevated risk, they did report a high prevalence of infestation, and young children are vulnerable to substantially greater health risks from improper pesticide use (Lu, Batt, Pearson, Walker, & Bravo, 2009; Turner, Wigle, & Krewski, 2010).

Our study had a number of limitations. Cross-sectional data limit conclusions about temporal order of measures. Characteristics such as age, poverty, and children's ages likely predate our measure of infestation in the past year; however, health and mental health outcomes may have occurred concurrent with, or prior to, infestations. Any effects of infestations in prior years were not captured, and outcomes with some latency could be underestimated. Asthma in particular is usually diagnosed before adulthood, and we have no data on incidence of new asthma among children in the respondents' households. Some infestations reported here may represent ongoing infestations, which may have different distribution and health outcomes, and risks related to pesticide use may depend both on cumulative exposure and time.

Our analysis relied on self-report to estimate infestation prevalence. Bed bugs are small, hide during the day, and change appearance in different life stages. This could lead to misidentification, which might be differential within subgroups (Reinhardt, Kramplic, Naylor, & Siva-Jothy, 2009). Media coverage may influence bed bug identification (Anderson & Leffler, 2008). Subpopulations may report differently due to stigma or to specific preserving health concerns. Bite sensitivity may also influence bed bug reporting, and population prevalence and distribution of bite sensitivity is largely unknown. Nevertheless, self-report may be the best measure of the impact of the bed bug resurgence; for example, some individuals with true infestations may experience less anxiety or stress from bed bugs than others who are not infested but fearful of infestation. As more information becomes available, self-report may prove to be an accurate marker of infestation levels.

Our survey was also limited because it qualified infestations as those requiring an exterminator, and factors such as cost, experience, cultural norms, and overall health

may have an impact on the use of pest control services. Lastly, New York City's population and housing stock is unique, diverse, and subject to local environmental characteristics and municipal policies that may have affected bed bug transmission and limit generalizability of these findings.

Despite possible reporting biases in our study, these findings may help evaluate and interpret other administrative data sources, such as New York City and other municipal levels of complaints and building violations.

Conclusion

Household and neighborhood-level poverty are associated with increased risk of bed bug infestations, suggesting that costs related to extermination may be an important barrier to pest control. As infestation may be transmitted among and within buildings; families living in disadvantaged neighborhoods with endemic control issues may be more heavily exposed to a greater reservoir of bed bugs, possibly furthering the high risk in an already burdened population and making neighborhood-level control more difficult. Building characteristics may play a role in transmission and should be investigated. Differentiated risk for younger ages and larger household size suggest a need for targeted community interventions and public education models.

Although no health or mental health outcomes including exacerbated asthma showed an association with infestation, differentiated prevalence, particularly among families with young children, may warrant targeted education around potential pesticide exposure. In future research, determining whether bite sensitivity is a confounder of infestation estimates may help validate self-reporting as a measure of infestation.

Acknowledgments: Thanks to Louis N. Sorkin, senior scientific assistant at the American Museum of Natural History, for expert advice in reviewing possible causal determinants of distribution. Thomas Matte, MD, assistant commissioner at New York City DOHMH, provided early assistance on the analytical structure. Also thanks to the DOHMH for the Community Health Survey data and Daniel Kass, assistant commissioner at DOHMH Bureau of Environmental Surveillance and Policy, for his helpful comments on the manuscript.

GRADE: A

Geospatial Analysis Investigating the Relationship Between Gestational Diabetes and Walkable Access to Unhealthy Food Sources in Bronx, NY

[redacted]

GEP 620
December 12, 2012

ABSTRACT:

Gestational diabetes mellitus (GDM) has been linked to adverse pregnancy outcomes. As a nutrition-dependent outcome, GDM has been associated with modifiable behavioral factors such as diet and exercise. There is currently no research to date that investigates the clinical outcome of gestational diabetes mellitus and its relationship to unhealthy food accessibility in an urban setting at the patient level. This study proposes to assess the association between walkable access to unhealthy food sources and risk of GDM among a cohort of 4,843 obstetric patients residing in Bronx, NY that initiated prenatal care in the year 2010. Interactive software applications containing patient medical records were previously employed to develop this cohort. Walkable access will be defined as living 0.25 miles or less to an unhealthy food source and locations of stores or restaurants of interest will be obtained from multiple commercial databases (ReferenceUSA and Dun & Bradstreet). Street network distances from each patient's geocoded residence to the *nearest* unhealthy food source will be calculated through a geographic information system. The adjusted odds ratio of GDM as a function of distance to an unhealthy food source will be obtained through logistic regression in order to determine the effect of unhealthy food environment on gestational diabetes risk.

BACKGROUND:

Gestational diabetes mellitus, also known as GDM, is defined as glucose intolerance associated with or first observed during pregnancy.[1] It has been estimated that this disease complicates approximately 7% of all pregnancies, afflicting more than 200,000 women each year.[1,2] Because the medical definition of GDM does not account for the possibility of glucose intolerance prior to pregnancy, these figures can be controversial given that preexisting, unrecognized intolerance can lead to overestimation.[3,4] However, gestational diabetes mellitus is undoubtedly one of the most common complications of pregnancy with long-established

adverse maternal and fetal outcomes.[1-3,5] Furthermore, important, often modifiable, risk factors have been identified as protective and causal determinants of GDM.[1,3-8]

Women diagnosed with gestational diabetes have notably worse pregnancy outcomes as compared to women without GDM. Patients with severe gestational diabetes are at increased risk for IUFD or intrauterine fetal death during the last 4 to 8 weeks of gestation. Moreover, regardless of severity, all cases of GDM are more likely to result in fetal macrosomia or large-for gestational age (LGA) newborns (greater than 4000g). In addition, maternal health can also be comprised as GDM increases the prevalence of hypertensive disorders, such as preeclampsia, and the need for cesarean delivery. Of more serious concern, women with gestational diabetes have elevated risk of developing type 2 diabetes after pregnancy. Similarly, their offspring have a higher likelihood of becoming obese, and developing glucose intolerance and/or diabetes as adolescents.[1,3]

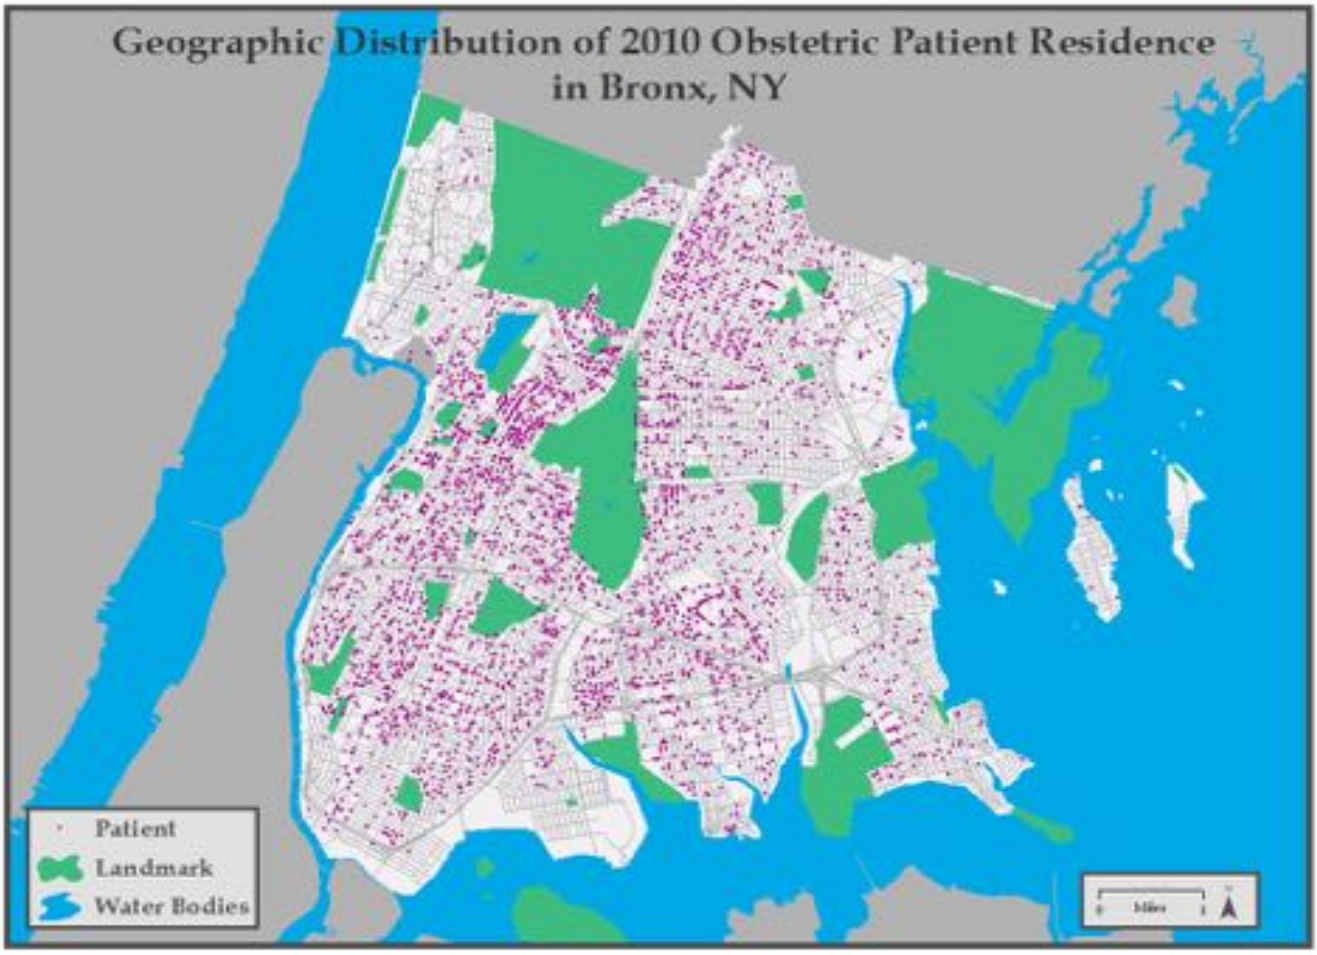
Gestational diabetes disproportionately affects certain populations. Therefore, the specific demographics of the population being studied are responsible for contributing to some of the variation among GDM statistics. Consequently, ethnicity, maternal age, parity (number of times a woman has given birth) and maternal birth weight serve as important unyielding risk factors. Both, maternal age and parity, demonstrate positive associations with gestational diabetes.[3,4,9,10] Interestingly, however, a mother's own birth weight seems to be inversely associated with her risk of GDM. Hence, the lower a woman's birth weight is as a newborn the greater her risk for gestational diabetes.[5] Ethnicity displays a more sporadic pattern as risk of gestational diabetes varies substantially across ethnic groups. GDM relative risk is higher for African Americans and Latino or Hispanic populations than for Non-Hispanic White populations. Further, South Central Asians demonstrate the highest risk. In general, foreign-born women have a higher prevalence of gestational diabetes as compared to US born woman.[8]

More importantly, body mass index (BMI), a modifiable factor, is arguably the most significant risk factor for gestational diabetes mellitus. As body mass index increases, the odds of having GDM concomitantly increases.[1,9,10] Consequently, diet, nutrition and exercise are important protective modifiers in the multi-causal web of GDM. Diets high in sugar content (glycemic load) and low in fiber are both positively correlated with disease. Specifically, the amount of dietary cereal and fruit fiber has proven to be extremely important in reducing risk, as a diet low

in both types of fiber is associated with more than twice the risk of developing GDM during pregnancy.[2] Accordingly, it seems likely that neighborhood food environment may influence the risk of complicating pregnancy with gestational diabetes as diet quality during pregnancy has been related to proximity to food sources.[11] Understandably, eating at unhealthy restaurants, such as fast food restaurants, is linked to high fat diets and increased BMI.[12] Likewise, in New York City, it has been proven that walkable access to unhealthy food stores is associated with higher prevalence of obesity.[13] Moreover, we predict that walkable access to unhealthy food stores in Bronx, NY will be positively correlated with increased risk of gestational diabetes mellitus.

Research Question:

Is walkable access to the *nearest* unhealthy food source associated with higher risk of having a pregnancy complicated by gestational diabetes mellitus in Bronx, NY?



DATA SOURCES:

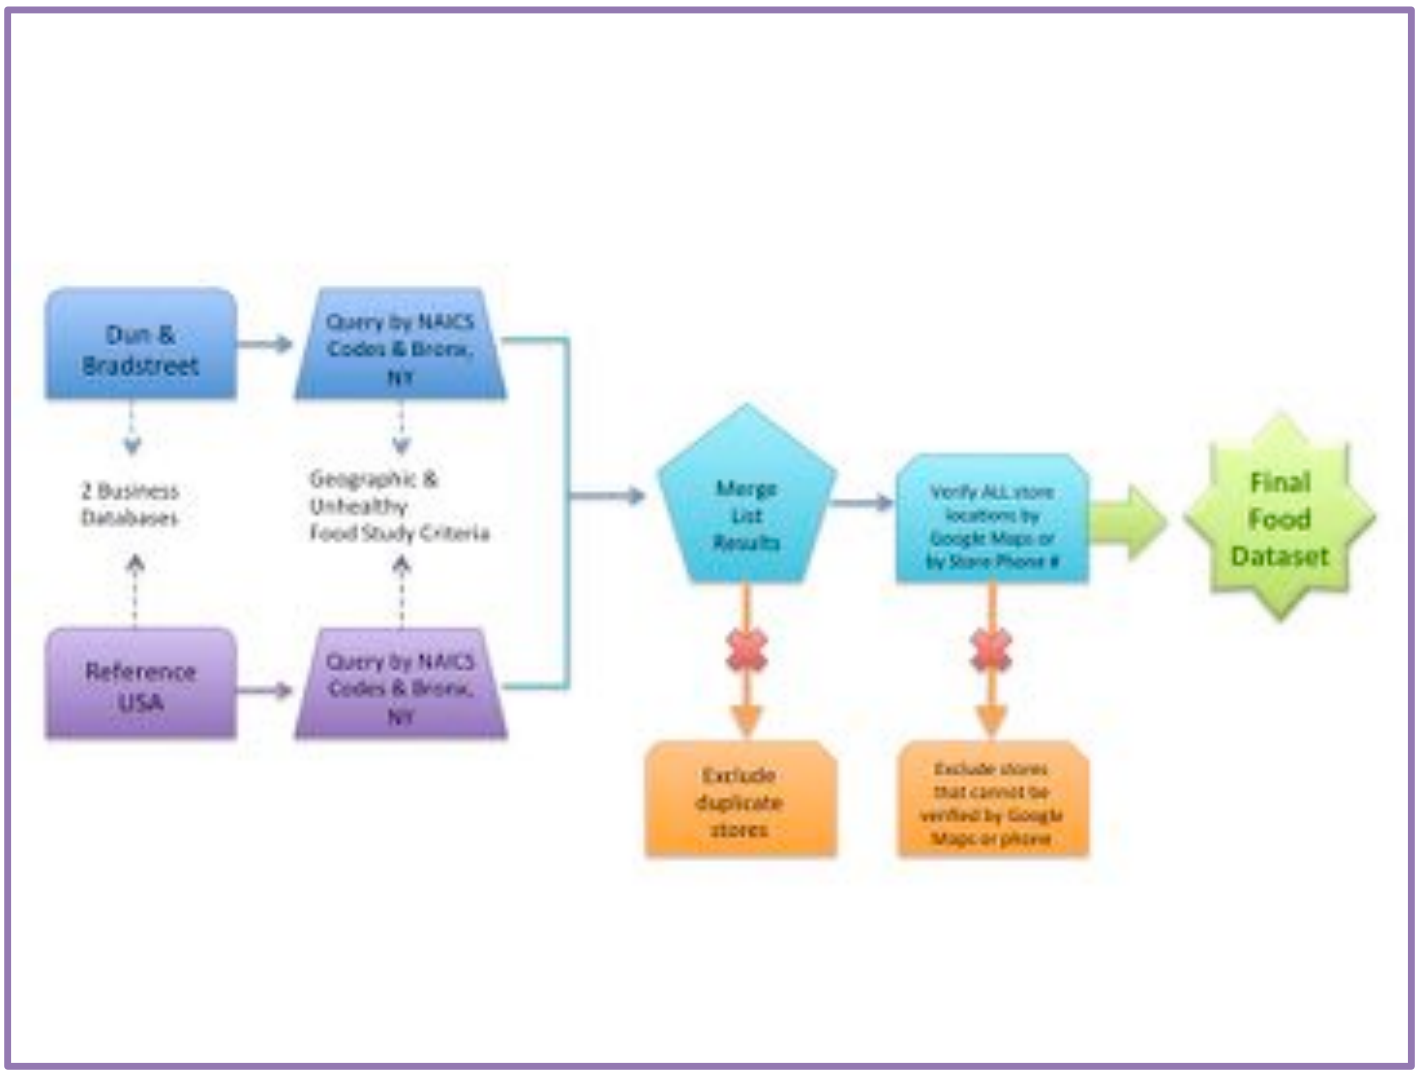
In order to test the validity of our hypothesis, answering our research question we have and/or need to obtain the following datasets:

Patient Data:

We have acquired a cohort of 4,843 patients, living in Bronx, NY, that delivered viable newborns at Montefiore Medical Center (Weiler Division) during 2010 from an interactive software known as Clinical Looking Glass (CLG). We used the Birth Report, a CLG application tool, to match mothers with infants born in our institution via medical record numbers, and to gather infant information such as birth weight, birth height, gestational age, and Apgar scores. In addition, AS ObGyn and EPF Web, two electronic charting systems, provided demographic characteristics and the prenatal course of our cohort as well as other relevant maternal and neonatal inpatient characteristics. Using this data, we spatially located our out-patient cohort by obtaining granular longitude/latitude coordinates through the CLG geocoding tool, which provides such values based on the patient's address recorded at first obstetric appointment (Figure 1).

Figure 1: Spatial Distribution of 2010 Montefiore Medical Center Patient Cohort

Unhealthy Food Store Data:



Reliable food source data within a given geographic locale can be cumbersome to obtain.[13,14] However, for a previous study (unpublished data Bottalico et al., 2012), we devised an exhaustive methodology to develop a complete healthy food source dataset for Bronx, NY. We will use a similar approach to compile an unhealthy food source dataset for this study (Figure 2). Based on previous studies,[13,15] we have defined unhealthy food sources as fast food restaurants, snack & nonalcoholic beverage bars, bakeries and candy & nut stores and have subsequently identified their respective North American Industry Classification System or NAICS code (Table 1).

Table 1: Defining Unhealthy Food Stores by NAICS code

Unhealthy Food Store	NAICS Code	Example
Fast Food Restaurants	722513	McDonald's, Domino's, Pizza Hut, KFC, Delis, Sandwich Shops
Snack & Nonalcoholic Beverage Bars	722515	Starbucks, Dunkin Donuts, Carvel
Bakeries	445291	LaSalle Bakery, Valencia Bakery
Candy and Nut Stores	445292	The Candy Box and Gelato Shop

We will use two commercial databases, Dun & Bradstreet and ReferenceUSA, to locate longitude/latitude coordinates, street addresses, and store phone numbers for all unhealthy food sources in Bronx, NY. Both databases will be implemented and queried by geographic boundary (Bronx, NY) and our 4 respective NAICS codes of interest (Table 1). We will also set our search criteria to include stores established by 2009 or earlier to be certain our derived food environment mimics a similar reality to that existing during the gestation period of our cohort. The list results will then be merged and duplicate stores as noted by matching coordinates or street address will be excluded. All stores will be verified by Google Maps street-view application or by store phone number. Stores that fail to be verified by either method will be excluded from the dataset and will be assumed to no longer exist. (See Figure 2)

Figure 2: Flow chart demonstrating method to develop our unhealthy food source dataset

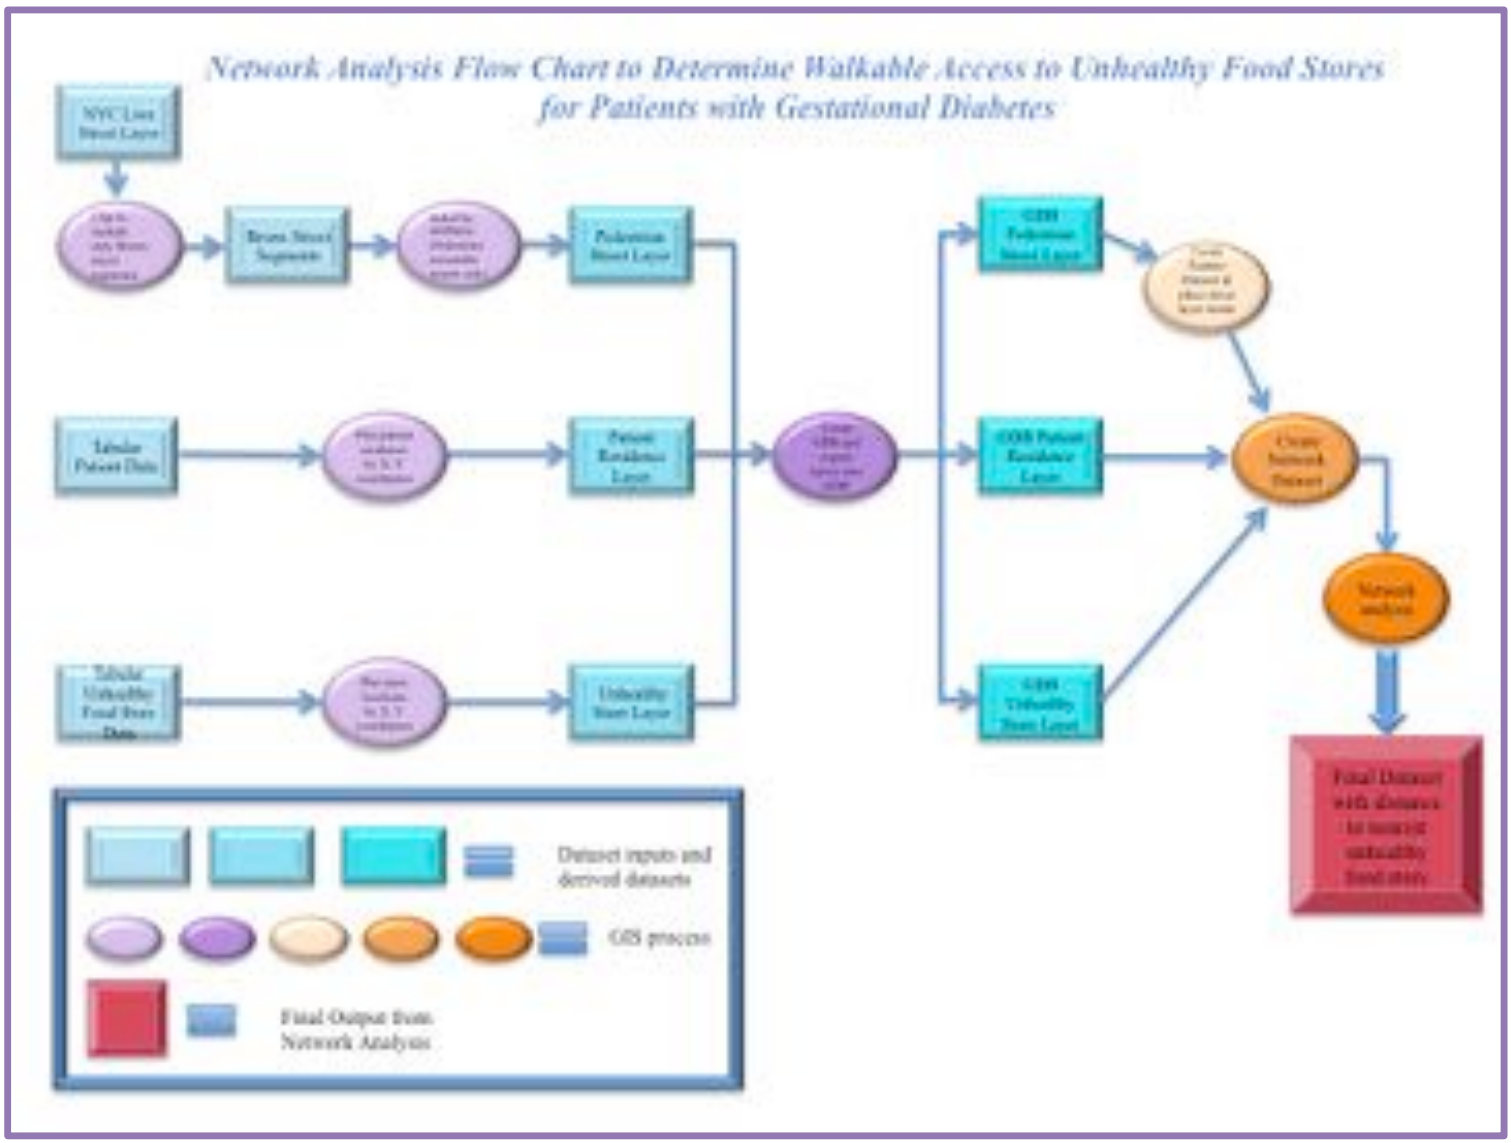
Street Network:

Our street network dataset has been obtained from New York City Department of City Planning LION Road Network. This dataset will be clipped to only include road segments in Bronx, NY and will be modified to include only pedestrian accessible street segments.

METHODS AND ANALYSIS:

Our study will use the above-stated datasets to perform network analysis in order to determine the distance to the *nearest* unhealthy food source for each individual in our cohort of 4,843 obstetric patients and has been approved by the Montefiore Medical Center Institutional Review Board.

The same diagnostic criteria as per Montefiore protocol will be used to determine whether a patient has GDM. A one-hour 50-gram load glucose challenge test (GCT) is used as a screening test. If the GCT yields a value of 130 or greater, the patient then undergoes the 3-hour 100-gram glucose tolerance test (GTT). If at least two of the four GTT values are abnormal the patient is diagnosed with GDM. The GCT screening test is performed twice during gestation, once at the first prenatal visit and again between 24-28 weeks gestation. If the GTT results at either of these visits meet the above-stated criteria then the patient is considered to have a pregnancy complicated by gestational diabetes. This data along with other outcome variables of interest will be appended to the patient dataset.



Tabular de-identified patient data containing ID numbers and x/y coordinates, unhealthy food store data and the street network dataset will be added to ArcGIS v10.0 software. Longitude/latitude (x/y) coordinates of our tabular data will be plotted accordingly. These plotted coordinates will then be exported into two separate layers (patients and unhealthy food store layers). Because the street network dataset spans NYC, the data will be clipped to include only segments in Bronx, NY. Additionally, we will select by attributes to include only pedestrian accessible streets. Selected attributes will subsequently be exported into a new street shapefile containing all pedestrian accessible street segments in Bronx, NY. A geodatabase will be created and the two layer files and one shapefile will be saved as *File and Personal Geodatase* features. All previous layers and shapefiles not within the geodatabase will be removed.

In order to create the network dataset, a feature dataset will be derived and the pedestrian street file will be imported. A new network dataset will then be created with the capability of modeling turns in street segments, but not elevation. Unhealthy food store locations from the respective file will be added as “facilities” and patient locations will be added as “incidents” in the network dataset. Network analysis will then be executed to determine the closest “facility” to each “incident.” In other words, distance in feet will be calculated to determine the nearest walkable path to an unhealthy food source for each patient. This distance will be converted from feet to equivalent miles and the resulting network dataset will be exported. We have defined walkable access as living 0.25 miles or less to an unhealthy food source. (See Figure 3)

Statistical Analysis

Exported de-identified patient data from ArcGIS will be merged with respective clinical data and inputted into SAS statistical software. Adjusted odds of gestational diabetes mellitus will be obtained through logistic regression in order to assess the effect of distance to unhealthy food sources as well as other relationships between covariables. The relationship between distance and GDM will be determined while controlling for variables such as race/ethnicity, maternal age, gestational age at first prenatal visit, parity, gravidity, spontaneous and elective abortions, type of insurance as well as others. We will also assess the relationship of interest conditioning on Medicaid/Uninsured patient status to serve as a proxy for socioeconomic status.

Figure 3: Network Analysis Flow Chart

Examining the literature:

Upon examining the literature, it is clear our study is novel in that we plan to merge granular clinical data mapped according to patient's street address with equally explicit data representing the unhealthy food environment of the patient's community. One such study investigated a similar relationship, specifically assessing the association between gestational diabetes and the general neighborhood food environment in New York City, in the absence of GIS software. However, no significant association was found. It should be noted that a substantially larger sample of patients were used, but only one commercial database was implemented (2001 Dun & Bradstreet) to define the entire food environment of the community. Unhealthy food was defined with similar subcategories, yet it was unclear how such subcategories were queried. Furthermore, patients were determined to have GDM based on ICD-9 coding rather than specific clinical indicators such as GTT testing. Patients and food sources were aggregated by census tract and logistic regression was performed controlling for covariables potentially modifying GDM risk. [6]

Two additional studies, interested in characterizing the neighborhood food environment, did employ spatial analysis software. Nevertheless, these studies also were ecological in nature. The first study, which we used as a foundation to develop our unhealthy food sources dataset (Figure 2), assessed the association between location of food stores and neighborhood characteristics by geocoding food stores to census tracts, estimating neighborhood wealth according to median value of homes, and determining the level of racial segregation by calculating the proportion of black residents. The local departments of environmental health and state departments of agriculture provided business addresses of food stores in the area of interest. Poisson regression was then used to determine the number of stores in relation to neighborhood wealth and racial composition. It was concluded that a larger number of supermarkets and convenience stores were located in wealthier neighborhoods comprising the study area. [15] The second study used the same methodology as the former ultimately determining that food environment is related to the prevalence of cardiovascular disease risk factors such as obesity, potentially lending support to our proposed hypothesis. [16]

Jeffery et al used a different approach to elucidate the association between food environment and obesity. Fast food restaurant locations were the independent variable of interest and were defined by Standard Industrial Code or SIC numbers. Both restaurants and participants were mapped at the street level and buffer analysis, rather than network analysis, was used to assess the

correlation between proximity of fast food restaurants and obesity. Spatial analysis was followed by logistic regression to control for underlying variables of impact. BMI of study participants was self-reported through telephone survey, serving as a proxy for obesity. This potential weakness in methodology may be linked to the null association. [12]

After applying a more rigorous analysis, Moore et al. were able to find a positive association between healthy diet and supermarket access. Once again, supermarket data was obtained from only one database, InfoUSA, and was queried by SIC code. Participants provided a questionnaire answering questions about their diet and were mapped by street address. Kernel density was performed using the Spatial Analyst extension of ArcGIS version 9.0 in order to calculate the density of supermarkets within 1 square mile of each participant's home. The density of supermarkets was weighted according to the Gaussian distribution to ensure supermarkets closer to participants' homes were weighted more heavily than distal ones. [17]

Impressively, Thornton et al analyzed the association even further, examining the individual consumption of fruits and vegetables and supermarket access using Euclidean buffers, road network buffers and kernel density analysis as described above. They even determined the optimal "walkable" distance for individuals without vehicles to be 0.25 miles. [18] Previously, this same network buffer distance was used to show that mobile food vending locations significantly affected children's negative eating habits after school hours in a predominately urban neighborhood. [19]

While 0.25 miles seems to be the optimal distance when interested in assessing walkable access to food stores, even larger road network buffers of 0.5 miles have been used to reveal the relationship between walkability to unhealthy food sources and obesity. One particular study derived their food dataset from the Dun & Bradstreet database querying by SIC codes. The same subcategories defining unhealthy food sources as described in our study (Table 1) were used. A positive association between obesity and such stores was shown by creating a 0.5-mile network buffer around each participant, highlighting all food sources of interest contained within the buffer. Density of store subcategories within each buffer was then determined and covariables were accounted for using multilevel modeling. [13]

RESEARCH SIGNIFICANCE:

More than 7% of women develop gestational diabetes mellitus during pregnancy, affecting greater than 200,000 women. Further, GDM is significantly associated adverse obstetrical and neonatal ramifications.[1,10] Despite efforts to control GDM through medication and improved nutrition in early pregnancy, the adverse effects of this glucose intolerance have wide-ranging implications for maternal and neonatal health.

The advent and implementation of mapping software is a relatively novel one, and has not yet been used to better understand obstetrical nutrition and gestational outcomes. Additionally, this study is unprecedented in that we have access to patient level clinical and demographic data as well as granular unhealthy food source data verified using an exhaustive approach. Our chosen geographic location, Bronx, NY, is equally important in that it is not only densely populated, but also contains a population with disproportionately higher percentages of minorities. Such populations have been shown to be at increased risk for development of GDM.[8,20] Furthermore, Bronx County suffers from much higher rates of poverty.[20] This is substantial as neighborhood wealth is positively associated with access to healthy food.[15] Therefore, developing a better understanding of the environmental factors involved in the development of gestational diabetes can ultimately help design interventions to more effectively address this public health need.

LIMITATIONS:

This study is not without limitations. As previously established, food environments can be extremely difficult to accurately define.[6,13] While we have developed a methodology to obtain a true, complete list of unhealthy food sources, there is no way to guarantee our model of the unhealthy food environment reflects the actual environment of our patients during 2010. Also, we have no way of measuring the mobility of our cohort throughout their gestational period. We are assuming the address self-reported at first prenatal visit is the primary residence of each patient during pregnancy. This could potentially lead to inaccurate network analysis measurements if individuals are mobile or moved during this period. Lastly, whether or not patients own or have access to a vehicle or use mass transportation as their primary means of travel may greatly impact these results. If, however, people purchase food primarily by walking, variables such as weather and neighborhood safety may also attenuate or enhance the observed relationship of interest.

FUTURE RESEARCH:

Based on our findings from the proposed study, additional research will be necessary to see if the observed effect can be replicated in other populations and spatial environments. We can enhance our knowledge concerning the impact of the environment on GDM by replicating this study with more rigorous tracking of patient's residence, and gathering information concerning ownership of vehicle(s) and/or public transportation use. Similarly, risk of gestational diabetes may be modified by incorporating weather patterns or seasonal changes as a variable within our model. With that said, it will also be intriguing to see if the same or inverse associations can be noted for other gestational outcomes. Future research will undoubtedly help us better understand the associations observed, thereby unveiling the true effects of environmental factors on gestational health.

Assignment #3
Research Strategy: Approach (Part "C")

C. Approach

C.1. Overview of Project

Obstructive Sleep Apnea (OSA) is one of the most common sleep disorders, affecting2-4% of the adult population (Miljuš, Tihaček-Šojić, Milić-Lemić, & Andjelković, 2014). OSA has been linked as an independent risk factor for hypertension (Kapa, Kuniyoshi, & Somers, 2008) and stroke (Dyken & Im, 2009), and is estimated to be responsible for over 38,000 cardiovascular deaths yearly (Öğretmenoğlu et. al, 2005). Studies have shown that the incidence of OSA in patients with cardiovascular disease (CVD) is 30 to 50 percent (Tiengo, Fadini, & Avogaro, 2008; Torres-Alba et. al, 2013).

The proposed project will study the correlation between Obstructive Sleep Apnea (OSA) risk and CVD severity among a sample of 320 people living in New York City. The participants for the study will be selected from four primary care centers in four different and racially diverse neighborhoods in New York City. The sample population will be individuals aged 18 years or older who have cardiovascular disease and self-identify as one or more of the following racial/ethnic groups: White, non-Hispanic, Black/African American, non-Hispanic, Hispanic and Asian. OSA risk will be measured with the ARES Watermark questionnaire (which includes Epworth Sleepiness Scale) and the Berlin Questionnaire. These questionnaires will provide information on daytime sleepiness, hypertension, snoring and BMI, all of which are independent risk factors of OSA. Other surveys will be used to collect socioeconomic and demographic data. In addition to examining the relationship between OSA risk and CVD severity by racial/ethnic group, we will also study if factors such as low awareness of OSA, lack of access to care, and low socioeconomic status play a role in the risk of sleep apnea among the sample, including how these factors vary by race/ethnicity.

C.2. Recruitment of Participants

The participants for the study will be recruited from four different primary care centers in New York City. Each primary care center will be selected from a racially diverse neighborhood in order to recruit equal number of participants from each racial group. The neighborhoods for each racial group will be selected using data from US Census 2010 data. Using Epiquery, where the reports on neighborhoods and race from NYC Department of Health and Mental Hygiene were available using Census data, Borough Park was shown to have highest percentage of White, non-Hispanic population; Bed-Stuy has high percentage of Black, non-Hispanic population; West Queens has high Hispanic population and Flushing has high Asian, non-Hispanic population. One primary care center from each of these neighborhoods will be the recruitment sites for the participants. Each primary care center will recruit 80 participants. The inclusion criteria for the sample will be: age 18 years or older, residents of that area, with no history of sleep apnea or any other sleep disorder, having CVD (such as hypertension,

Commented [A1]: OVERALL

- Please proofread
- Beef up recruitment write up
- Justify your N
- Clarify measures and stats in data analysis plan

Commented [A2]: Worldwide? In the US?

Commented [A3]: There's a rule somewhere in APA – unless it's a % or some unit of measure, if the number is less than 10 you write it out.

Commented [A4]: Spell out acronyms upon first usage

Commented [A5]: This can all be condensed. We don't need to know the nitty-gritty of how you got the neighborhoods (though cite EpiQuery). Just say the neighborhood and % of white/Hispanic/whatever pop.

Commented [A6]: "diagnosis" rather than "history"?

stroke, arrhythmia, heart attack etc.), be the only member of the family participating in the study and consent to participate. The exclusion criteria for the study is: having a history of or existing sleep apnea or other sleep related disorder, being pregnant and impaired cognitive or functional ability.

Commented [A7]: So are you not using race/ethnicity as an inclusion criteria? How are you sure you are going to get enough of each to compare?

C.3. Study procedures

C.3.a. Recruitment and sampling procedure

The participants will be recruited at primary care centers. Surveys will be used to collect data and each participant will be paid $20 for their participation. All the surveys will have two copies of the consent form, one for the participant to keep and other to be attached with the completed survey. Both copies of the consent form will be signed by the participants before filling the survey. A total of 80 participants will be recruited from each racial group and each primary care center.

Commented [A8]: You need way more details about how you are recruiting here.

C.3.b. Informed Consent

Participation in the proposed study will be completely voluntary. An IRB approved consent form will be attached to the survey. The participants will be required to read and sign the consent form before filling the survey. The consent form will include information about the study, the principal investigator, the goal of conducting the research study and criteria to be in the study as per the IRB rules for writing a consent form. The recruitment approach and data collection procedure will comply with the Health Insurance Portability and Accountability Act (HIPAA) laws that protect the privacy of patient's medical data and health information.

C.3.c. Quantitative Data Collection Procedures

The method used for data collection will be surveys. Along with surveys, neck measurement will be taken for each participant using a measuring tape which is required to complete scoring for risk apnea in ARES Watermark Questionnaire.

C.3.d. Incentives

All the participants will be paid $20 for their participation. After completion of the survey, participants will be given an information packet containing information about sleep apnea, how to identify symptoms of sleep apnea and some information on resources available in their community (such as nearest sleep centers etc.).

C.4. Measures.

Commented [A9]: How is CVD severity measured?

The measures used for data collection are: ARES Watermark Questionnaire, which includes the Epworth Sleepiness Scale, the Berlin Questionnaire and survey questions about demographics and socioeconomic status.

The Apnea Risk Evaluation System (ARES) Questionnaire will be used to identify people at risk of OSA. The questionnaire includes demographic and anthropometric data, diseases associated with OSA risk (i.e. History of stroke, hypertension, diabetes or any heart disease) or history of sleep apnea, the Epworth Sleepiness Scale, and frequency rating for snoring, waking

Commented [A10]: So this measure will result in a nominal outcome variable, right?

up choking and witnessed apneas. The Epworth Sleepiness Scale included in the ARES questionnaire is an eight-item questionnaire that measures daytime sleepiness which is one of the most common symptom of sleep apnea. Using ARES questionnaire, individuals will be assigned as having “no significant risk,” “low risk,” or “high risk” of OSA. A study validating the ARES questionnaire has shown that ARES has a sensitivity of 0.94, specificity of 0.79, positive predictive value of 0.91 and negative predictive value of 0.86 (Levendowski et al, 2007).

The Berlin questionnaire is an 11-item questionnaire that includes questions about risk factors for sleep apnea, including snoring behavior, fatigue, and obesity or hypertension. The Berlin questionnaire is a validated instrument that is used to identify individuals who are at risk for OSA in primary and some non-primary care settings. The questionnaire was validated by Chung et al. in 2008. (Chung et. al, 2008).

The dependent variable for the study is OSA risk among people with CVD and the independent variables are demographics, race and socioeconomic factors (education, marital status, income, and employment).

C.5. Data analysis.

C.5.a. Data storage and cleaning, Quality Assurance

The collected data will be entered into SPSS and will be stored in a separate computer designated for use by OSA study coordinator and data manager. All the participants will be given a study Id or an alphanumeric identifier to ensure the safety of participant and the validity and integrity of the data. Such identifiers linking personal data to subjects will be maintained in a separate and secure file. The principal investigator, study coordinator and data manager will have access to the file containing personal information of the participants such as name, age, sex, address and contact information. The data will be coded and then entered into SPSS. Statistical analysis will be done using SPSS and data manager will assist the principal investigator in analyzing the data.

C.5.b. Data analysis to Achieve Aim 1

Hypothesis 1: Among CVD patients, CVD severity increases the risk of OSA.
The quantitative distribution of the variables will be expressed as descriptive statistics (frequencies, means and standard deviations, and range). Chi-square and independent t-test will be used to analyze the relationship between CVD and OSA risk among the sample.

C.5.c. Data analysis to Achieve Aim 2

Hypothesis 2: Among CVD patients, racial/ethnic minorities are at increased risk of OSA than white. Non-Hispanic patients..
To understand the correlation of race and risk of OSA, differences between groups in terms of level of OSA risk, age, neck size, etc., will be analyzed using ANOVA and correlation analysis.

References

Commented [A11]: Nominal or continuous

Commented [A12]: Is this nominal like ARES or is it continuous?

Commented [A13]: I have no recollection of your specific aims (sorry!), but just make sure that THIs matches THAT.

Commented [A14]: Be more specific about what stats you are going to use for what measures (that is why I was asking about the nominal vs, continuous nature of the variables above)

Commented [A15]: Neck size is a part of ARES (which means it’s a part of risk of OSA), right?

Commented [A16]: More specific please. Whom vs. whom, how many groups, what are the independent and dependent measures, which stats for each, etc. Even if it’s a “We are comparing [everything] by [everything]. For example…” type of elaboration, show the reader that you know what an ANOVA is and how it would be used.

A review of types of safer sex practices among adolescent and young adult females in the United States

A Paper Presented to the Faculty of the Department of Health and Nutrition Sciences

Brooklyn College

In Partial Fulfillment of the Requirements for the Degree of Master in Public Health

By:

2014

Abstract

Introduction

Sexually transmitted diseases (STDs) remain an international problem that disproportionally affects the adolescent and young adult population (East, Jackson, O'Brien, & Peters, 2007). Adolescence is defined as the years between 15 and 19 years old. According to World Health Organization (WHO), young adult refers to the overlap between adolescence and post adolescence between the years of 15 and 24 (East, Jackson, O'Brien, & Peters, 2007). Sexually transmitted diseases are infections that can be acquired through sexual activity with an infected partner (Centers for Disease Control [CDC], 2011; National Institute for Health [NIH], 2014). There are over twenty types of STDs (NIH, 2014). Herpes simplex virus type 2 (HSV-2), or genital herpes, hepatitis B (HBV), and human immunodeficiency virus (HIV) are all lifelong infections that make up about a quarter of STDs, but others can be treated and cured if detected and diagnosed (CDC, 2013).

Commented [A1]: To respond to your question, I think your intro, well your first 12 pages really, is more of a parabola than a triangle! I literally couldn't make figure out what everything was where it was (why am I reading about race in 3 places, why are we talking about how kids get all the STD's AGAIN? And you taught me all about condoms like 6 times!)

Female Adolescents and Young Adults

Commented [A2]: Sentence case your headings

Women may be less likely than men to have symptoms of STDs, or their symptoms may be less noticeable. For example, men may develop sores on their penises from STDs which are more visible than a genital ulcer inside the vagina (CDC, 2011a). Many adolescent females also have little knowledge of the symptoms of STDs allowing the disease to go undetected and thus undiagnosed (East, Jackson, O'Brien, & Peters, 2007). Health complications can affect men and women, but young women face the most serious long-term effects, including infertility (CDC, 2014). Other risks associated with untreated STDs include pain, cervical cancer, and pelvic inflammatory disease (Paterno & Jordan, 2012).

Commented [A3]: This paragraph should start with the sentence, "Female adolescents and young adults are important because…"

Young women are at a higher risk for STDs and HIV due to biological, social, and behavioral factors. Women are more vulnerable to sexually transmitted diseases because of

higher rates of "cervical ectopy" (Chambers & Rew, 2003). Cervical ectopy is a common biological process that can occur during adolescence. "Cervical ectopy is thought to increase risk … by exposing columnar epithelium to a potential infectious inoculum" (Lee, Foley, & Tobin, 2006). Adolescent females are also at higher risk of for STDs because of typical gender roles in sexual relationships. Culturally, females may have less power to negotiate contraceptive and/or condom use (Chambers & Rew, 2003). A female's decision to not use a condom may be decided on her desire to please her partner. Female adolescents are also more likely to be coerced into a sexual activity than male adolescents (Chambers & Rew, 2003).

Predicting contraceptive use

In general, studies show that a multitude of variables predict whether or not an individual will practice safe sex. These variables include race, ethnicity, age, education, religion, age of sexual debut, parental views and, relationship status (Daniels, Mosher, & Jones, 2013; East, Jackson, O'Brien, & Peters, 2007). While virtually all sexually active women have stated that they have used at least one form of contraception at some point in time, many women still harbor misconceptions about contraception (Daniels, Mosher, & Jones, 2013).

Commented [A4]: Are we talking about everyone or just adolescents. Because I thought we were talking about everyone, which is what I added the "In general"

Commented [A5]: I don't know why this is here. I don't know what this paragraph is about.

Often, adolescents do not realize there is a difference between contraceptive measures and safe sex. This age group often does not differentiate between the two and tend to believe that the terms are interchangeable (East, Jackson, O'Brien, & Peters, 2007). Despite the proven effectiveness of condoms against pregnancy and STI's, condom use remains low among both male and female adolescents. Unfortunately, male condoms only provide modest protection against pregnancy when compared to other forms of protection (Tyler et al., 2014). Conversely, non-barrier forms of protection such as oral contraceptives provide high protection against pregnancy, but do not provide any protection against STIs (East, Jackson, O'Brien, & Peters,

2007; Tyler et al., 2014). With any form of protection, it is imperative for use to be consistent and correct in order to achieve the highest level of effectiveness offered by the protective measure (Tyler et al., 2014).

Misinformation or lack of knowledge can inhibit condom use among adolescents. Many adolescents associate condom use only with pregnancy prevention. Holding true to that belief, once adolescents switch to contraceptives there is often a decrease in condom use among adolescents. Only one in six female adolescents use both condoms and another form of contraception (Chambers and Rew, 2003). Adolescents are often confused by the ambiguity of the terminology "safer sex" and "contraception". Safer sex applies to preventing the transmission of diseases as well as preventing unplanned pregnancy. Contraception only applies to avoiding pregnancy (East, Jackson, O'Brien, & Peters, 2007). The ambiguity leads to the misconception that even non-barrier contraceptives are safe sex practice. The CDC recommends abstinence and condom use as a preventive measure for adolescents (Chambers & Rew, 2003). While condoms provide protection against both STDs and unplanned pregnancy, the oral contraceptive pill, the most successful contraceptive, does not provide protection against STDs (East, Jackson, O'Brien, & Peters, 2007). One in five adolescents believes that an oral contraceptive pill is effective against the risk of STDs (KFF, 2013b).

With any form of protection, it is imperative for use to be consistent and correct in order to achieve the highest level of effectiveness offered by the protective measure. Research shows that adolescents are more inconsistent with safe sex measures than adults (Tyler et al., 2013). Another misconception among adolescents is regarding the uses of "withdrawal" and "delayed application of condoms." Over one third of sexually active adolescents that report condom use admit to not using a condom prior to any genital contact (de Visser, 2004). While this practice

may protect against pregnancy, it does not protect against STDs, and it is imperative for adolescents to understand the difference. As discussed previously, adolescents are more likely to use condoms for pregnancy prevention rather than protection against STDs. Since this population is using condoms to avoid pregnancy, their perceived risk of STDs is lower than it should be (de Visser, 2004). One third of adolescents engage in oral sex, yet only one in five adolescents believe that STDs can be transmitted through oral sex (KFF, 2013b). With this belief, adolescents engaging in oral sex are not using protective measures against STDs, such as condoms. Many adolescents feel that oral sex is a safer form of sex; in fact 13% of adolescents who have not engaged in sexual intercourse have had oral sex (KFF, 2013b).

While each form of protection exhibits its own merits, there is no form that can provide total protections on its own (Bearinger & Resnick, 2003). Since forms of contraception each carry their own benefits and risks, Healthy People 2020 encourages dual use protection among adolescents and young adults to create a more complete safer sex practice (HHS, Healthy People 2020, 2013). In order to achieve the highest rates of protection against both STIs and pregnancy, it would be prudent to encourage the dual use of condoms and non-barrier pregnancy protection. To understand how to achieve higher dual use rates in adolescent and young adult American females, we need decipher the factors associated with the various measures of safer sex practices.

Table 1.
Classification of types of safe sex practices

Category	Description
Condoms only	Male or female condom
Non-barrier only	-Hormonal methods (oral contraceptives, patches, injections, vaginal rings, emergency contraceptive

	pills) -implantable rods intrauterine devices
Dual Use	Male or female condom plus a non-barrier form of contraception (see above)
No protection	Includes withdrawal and fertility awareness based methods (ovulation tracking)

Background and Statistical Overview

STDs represent a serious public health problem, with an estimated prevalence of 110 million cases in the United States and an estimated 20 million new cases each year (Centers for Disease Control [CDC], 2014). In addition to the health consequences of STDs, there are also

Commented [A6]: I am having a hard time reconciling the previous 7 pages with this and subsequent sections. There seems to be a lot of redundancy and the "2 chunks" should be integrated more.

serious financial implications. The CDC estimates that STDs cost the United States about $16 million per year in healthcare costs (2014). Moreover, the actual prevalence rates of some STD cases likely surpass the numbers reported by the CDC, due to undiagnosed cases and STDs such as human papillomavirus (HPV) and genital herpes that are not reported to the CDC. (CDC, 2013).

In the United States, almost half of the new cases of STDs occur among adolescents and young adults aged 15-24 years old (CDC, 2013). Every year approximately one in four sexually active 15-24 year olds will contract some type of STD (Kaiser Family Foundation {KFF}, 2013a). Young adults and adolescents aged 15-24 years old account for 26% of newly reported cases of HIV mostly acquired through sexual contact (KFF, 2013b).

Aside from their high risk for STDs, female adolescents in the United States are also at a high risk for unintended pregnancy. In 2009, the birth rate among U.S. teens decreased to 39.1 births per 1,000 females, a 37% decrease from the birth rate of 61.8 per 1,000 females in 1991. Despite the decline in adolescent pregnancy, the United States still has the highest rates in the developed world (Chambers & Rew, 2003). In fact, the teen birth rate in the United States is as much as nine times higher than other developed countries (CDC, 2011b). Teen pregnancies account for roughly 10% of births in the United States (Patel & Sen, 2012). One in four of non-marital births in 2004 occurred among adolescent females (Basch, 2011).

Among white teens, the birth rate was reported as 25.6 per 1,000 females (CDC, 2011c). African American and Hispanic women still report higher rates of unintended pregnancy than white women (Paterno & Jordan, 2012). In 2009, the birth weight for black teens was 59 per 1,000 females and 70.1 per 1,000 females among Hispanic adolescents (CDC, 2011c). Teen pregnancies in the United States are associated with high economic and social costs. The total

Commented [A7]: Shouldn't this be in the race section down below?

U.S. government expenditure of teen pregnancy was $11.3 billion in 2006 (Patel & Sen, 2012). Births born by adolescents are more likely to have lower birth weight and higher rates of death in infancy than seen in pregnancy from adults (CDC, 2011c). Teen mothers also experience adverse effects. Studies indicate strong associations between teen pregnancy and low employment, low levels of education, and low socioeconomic status among teen mothers (Patel & Sen, 2012). Teens that become pregnant are less likely to finish high school and college. Children born to teenage mothers are also more likely to become teen moms themselves (Basch, 2011).

Racial and Ethnic Differences

Little research exists on the sexual practices of Asian/Pacific Island adolescents, but adolescents of other races and ethnicities tend to have higher rates of STDs and pregnancy than Asian and Pacific Island adolescents. It is important for researchers to further assess the sexual behavior of Asian and Pacific Island adolescents, as Asian and Pacific Islanders are one of the fastest growing populations in the United States (Schuster, Bell, Nakajima, & Kanouse, 1998). Research indicates that white adolescents are 2.3 times more likely to communicate about STDs than Asian adolescents. Asian adolescents may be a more vulnerable and harder to reach population than white adolescents (Hou & Basen-Engquist, 1997).

Commented [A8]: Differences in what? First you are talking about STDs (and only telling me about Asians versus Whites). Then in the second paragraph you are talking about sexual behavior.

Commented [A9]: You really shouldn't open with Asians – they are the smallest and least risky group and usually come AFTER you have discussed black/white/Hispanic differences.

According to the 2011 Youth Risk Behavior Survey (YRBS), about half of (47.4%) of American high school students have engaged in sexual intercourse (CDC, 2011c). Among females, black students are more likely to engage in sexual intercourse (58%) than white (45%) and Hispanic (45%) adolescents. For male students, black adolescents (72%) reported the highest rates of sexual intercourse, when compared to Hispanic (53%) and white (40%) students (CDC, 2011c). Overall, there was a decrease in sexual intercourse among male and female

students, but there was no decline among white female students, Hispanic female students, or Hispanic male students (CDC, 2011c). As stated previously, data regarding sexual activity among Asian adolescents is limited, but studies do show Asian American adolescents have lower involvement in sexual activity than other races (Tosh & Simmons, 2007). A survey of California students found that 27% of Asian American students had ever engaged in sexual intercourse, compared to 50% of white students. While involvement in sexual intercourse may be lower among Asian American adolescents, once engaged in sexual behavior Asian Americans tend to engage in similar behaviors as other ethnicities. For example, the uses of alcohol during sex as well as rates of condom use have been reported as comparable to the rates among other ethnicities (Tosh & Simmons, 2007).

Adolescent Risky Behavior

Adolescents place themselves at a higher risk for STDs because of their risky sexual behaviors (CDC, 2011b). These behaviors include engaging in unprotected sex, having multiple partners, partaking in sexual activities with risky partners, early sexual debut, alcohol abuse, and substance abuse (Chambers & Rew, 2003; Polacek, Coker, Lewis, Minter, Viela-Perez, & Scott, 2008). Early sexual initiation is also associated with high numbers of lifetime sexual partners (Tosh & Simmons, 2007). 26% of female students report having more than one sexual partner. 11% of high school students report having more than four sexual partners (KFF, 2013a). Many adolescents judged their partners' risk of transmitting disease by his/her physical attributes. That is, if an adolescent felt a potential partner seemed "clean", the adolescent used that determination as an indicator of risk (East, Jackson, O'Brien, & Peters, 2007). One in five adolescents believe they would "just know" if their partner had an STD (KFF, 2013b). Adolescents often engage in sexual behavior with risky partners. For example, an adolescent female who engages in sexual

Commented [A10]: Haven't we gone over this already?

intercourse with a partner who used drugs or alcohol beforehand was less likely to use a condom (Staras, Livingston, Maldonado-Molina, & Komro, 2013). As male condom use remains inconsistent, the rates of STDs continue to rise (East, Jackson, O'Brien, & Peters, 2007).

STD risks for adolescents

Even though abstinence is the most reliable way to avoid STDs acquired through sexual intercourse, latex condoms have proven to greatly reduce the risk of STDs when used correctly and consistently (CDC, 2013). Reports of condom failure are usually due to incorrect use such as condom breakage, slippage, or leakage. Condom users also need to understand that it is imperative to use a condom throughout the entire sexual act in order to further reduce the risk of STDs (CDC, 2013). Despite the proven effectiveness of condoms, of the adolescents who have had sex in the past month, one in four males and about one in ten females did not use a condom (Department of Health and Human Services [HHS], 2013). According to the 2011 YRBS, 12.9% of American high school students did not use any sort of contraception in their last sexual encounter (CDC, 2011c). The rates of condom use among adolescents decrease across grades. Bach's study reveals condom use decreased from 69.3% amongst 9th grades to 54.2% amongst 12th graders (Basch, 2011) . These statistics indicate the continued public health problem affecting this population and further enforces the importance of understanding the predictors of safer sex practices.

In order to decrease the rates of STDs and unintended pregnancies among the American female adolescent population, it is imperative to understand who is using which forms of sexual protection and why. Despite the associated risks of unprotected sex, adolescents continue to engage in sexual behaviors without a method to protect against pregnancy or sexually

Commented [A11]: Isn't this the same as the previous?

Commented [A12]: I moved this chunk from your findings section.

transmitted diseases (Peterno & Jordan, 2011). Understanding the factors behind safer sex practice decisions can help to create effective sexual health interventions for adolescents and young adults. Knowing why young women do not use preventive measures could help health educators prevent unintended pregnancies and STDs (Paterno & Jordan, 2007). The factors behind safer sex practices range widely from demographics to social issues.

Much of the previous research has been focused on condom use as an indicator of safer sex practices, but Healthy People 2020 encourages dual use protection among adolescents. Dual use is defined as combining the use of a condom with a form of hormonal contraception such as oral contraceptives (Morroni, Heartwell, Edwards, Zieman, & Westhoff, 2014). As stated previously, no one type of contraceptive provides full protection against both STDs and pregnancy, which is why dual use is now being recommended (Tyler et al., 2014). Since the adolescents in the United States report lower dual use than other developed countries, it is important to understand the factors behind each type of contraceptive – including no protection, condom use only, non-barrier protection only -- to properly address the issues that may affect dual use.

Methodology

A literature search was conducted using peer-reviewed articles gathered from online databases as well as statistical reports collected from government and foundation websites for my research. I performed my search using key words such as “condoms,” “adolescent condom use,” “predictors of condom use,” “risky sexual behavior and adolescents,” ” parental views on condom use,” ” rates of STDs,” “oral contraceptives and adolescents,” “dual use and adolescents,” and “sexual education”. My search has been limited to English language only

publications published primarily between 1997 and 2014. The search was not limited to studies in the United States, in order to ascertain if adolescents and young adults were adversely affected in the U.S. as compared to other countries. Studies that focused primarily on males and adults over the age of 24 were excluded. Overall 28 studies were reviewed.

Commented [A13]: But do you go into this at all? I don't see it in the results, and if there were international comparisons you should mention how many articles had this in that first paragraph of your findings section.

Findings

This paper explored the differences amongst female adolescents and young adults, ages 15 to 24 years of age, who choose various forms of protection for safe sex practices. In a review of 28 research articles, I examined the attributes of female adolescents and young adults who use contraception within the following four categories: no protection, condoms only (e.g. male and female condoms), non-barrier protection only (e.g. oral contraceptives, intrauterine devices, and shots), and dual use, i.e., condom and non-barrier protection together. As shown in Table 2, demographic and social factors associated with each category of contraception were examined.

Condom use only

Commented [A14]: I would add Level 3 headings here to help break up the section. I made some suggestions, be keep in mind it all has to align with what is on the table.

Condoms refer to the use of either male condoms or the less popular female condoms. Condom use among adolescents and young adults is important in preventing against the spread of STDs (Tyler et al., 2014). Sixteen studies focused on condom use among adolescents and young adults. Most research showed condom-only practices were most prevalent among the adolescents and young adolescents. While condoms do afford protection against both STDs and pregnancy, the protection against pregnancy is quite modest. Condoms have 2% pregnancy rate when used ideally and up to a 17.4% pregnancy rate when used typically (Brown, Hennessy, Sales, DiClemente, & Salazar, 2011; Ott, Adler, Millstein, Tschann, & Ell, 2002; O'Leary, 2011). Since the condom is a proven form of contraception that also protects against sexually

Commented [A15]: Move up or out, you don't need this here.

Commented [A16]: When you talk about each study below, be sure to be clear if you are talking about male and female adolescents or just female.

Commented [A17]: As compared to whom?

transmitted diseases (Witte, Stefano, & Hawkins, 2010), it is important to understand what makes individuals more likely to practice appropriate condom use.

Demographic factors. Certain demographic factors can have an effect on the likelihood of condom use among adolescents and young adults. These factors include race/ethnicity, religion, and socioeconomic status (Manlove, Ikramullah, & Terry-Humen, 2008; Paterno & Jordan, 2012). For example, according to the 2011 YRBS, 34.7% of African American adolescents reported not using a condom in their last sexual encounter, where as 41.6% of Hispanic adolescents reported not using a condom. The YRBS also stated that 40.5% of White adolescents and 33.8% of American Indian/Alaskan adolescents reported not using a condom. The percentage of Asian adolescents not using a condom was reported as N/A in the YRBSS (CDC, 2011c). While none of the previously stated percentages are desirable, it is clear that there are discrepancies in condom use among various populations. According to Manlove, Ikramullah, and Terry-Humen, African Americans adolescents report higher condom use. This could be attributed to greater communication between parents and children regarding sex (2008). Research also indicates that non-white women are more likely to acquire an STD (Paterno & Jordan, 2012) and first generation Hispanic adolescents are only half as likely as white adolescents to report consistent condom use (Manlove, Ikramullah, & Terry-Humen, 2008). Adolescents and young adults who are either African American or Hispanic were more likely to use condoms alone if compared to white adolescents (Tyler et al., 2014; Cavazos-Rehg, 2010).

Perceived risk. An important factor of condom use among adolescents and young adults was the perceived risk of STDs. Those who reported a high self perceived risk of STDs continued to report consistent rates of condom use (Ott, Adler, Millstein, Tschann, & Ellen, 2002). When a female felt there was a high risk of STD, she was more likely to use a condom

Commented [A18]: I feel like this can be moved up somewhere – maybe somewhere where you are telling me about condoms in general.

Remember that your results section should only have results in it! It is often the shortest section of a paper.

Commented [A19]: Throughout: I am not clear when you are talking about both male and female or just female.

Commented [A20]: Are you going to talk about these other variables?

Commented [A21]: Were the differences found to be statistically significant?

Commented [A22]: Doesn't this contradict your previous finding? It's fine if it does, but just say some blanket statement like, "Among adolescents, racial and ethnic differences have been found in relation to rates of condom usage, however these findings are inconsistent."

during sex. Partner type is also a significant factor in condom use among female adolescents. Research indicates that female adolescents and young adults are more likely to use condom only protection with casual partners (Tyler et al., 2014).

Health insurance and education were also significant variables among females who use condoms only. Those with no health insurance were more likely to use condoms only. This may be due to a lack of access to prescriptions (Tyler et al., 2014). Adolescents who are looking for low cost measures of protection also report condom only use (Cavazos-Rehg, 2010). Females with less than a 12th grade education were also more likely to report condom only use over dual use. The research did not implicate reasons for this finding, but education did seem to be a consistent factor across various studies.

Partner type. Another factor related to condom-only use included females entering into new relationships. Females who did not yet trust their new partners used condoms more than those in steady relationships. Overall trust is an important issue in female adolescents deciding to use a condom. Those who report high levels of trust felt that they no longer needed to use a condom (Roye, 2001). Another interesting factor associated with condoms-only use was found among females without previous pregnancies. Females who were never pregnant were more likely to use the condom-only method over dual use methods (Tyler et al., 2014).

Current age and age of sexual debut also play a role in females using only condoms for safer sex protection. Younger adolescents may be more likely to use condoms only than other forms of contraception. Some studies indicated that those between 15-19 were more likely to use condoms only when compared to older adolescents. Other studies showed that those less than 17 were more likely to use condoms only (Tyler et al., 2014; Ott, Adler, Millstein, Tschann, Ellen, 2002). Generally, those towards the younger end of the 15-24 year old age range are more likely

Commented [A23]: Is this a proxy for age?

Commented [A24]: I don't know if this should do under demographics, or get their own subsection or what.

Commented [A25]: Again, you are pairing these so I am not sure what to call this in the level 3 heading. Maybe just "Current age and age of sexual debut"?

to use condoms only. Those who initiated in sexual intercourse at a later age seemed to use only condoms for protection. Tyler et al. (2014) found that those who were 18 or over at sexual debut used condoms only as their regular form of protection. Adolescents who used a condom at their sexual debut were also more likely to consistently use condoms during later encounters than those who did not use a condom at sexual debut (Shafli, Stovel, & Holmes, 2007).

No protection

No protection is unprotected sex, but can include the use of methods that do not provide effective protection against STDs and pregnancy. Withdrawal, also known as the pull out method is considered in the no protection category. Despite the high levels of risk faced by adolescents, many still forgo protective measures. No protection is often associated with incorrect beliefs among adolescents and young adults. Many factors can contribute to unprotected sex among adolescents and young adults. Very often the lack of protection can be related to a partner's beliefs. According to the CDC YRBSS, while 35.2% of female adolescents were sexually active, 15.7% did not use any form of protection (CDC, 2013c).

Demographic factors. Higher rates of unprotected sex have been associated with Hispanic adolescents and young adults (Committee of Adolescent, 2013; Cavazos-Rehg, 2010). According to 2013 YRBSS, 23.7% of Hispanics, 21.2% of blacks, 11.9% of whites, and 13.7% of those with multiple races participated in unprotected sex. The survey did not provide statistics for Asians, Native Americans, or Native Hawaiian/other Pacific Islanders because the subgroup sizes were too small to produce significant findings (CDC, 2013c). Lower socioeconomic status may be associated with higher rates of risky sexual behavior among adolescents, which includes not using protection during sex (Manlove, Ikramullah, & Terry-Humen, 2008). Rates of unprotected sex are lowest among those with some college education (Tyler et al., 2014).

Commented [A26]: Move all this. You are interpreting in the results section and you shouldn't do that.

Commented [A27]: Not sure how to make this match the table, where SES isn't epresented.

Commented [A28]: What is this source?

Formal and informal sexual education. Research by Manlove and associates indicates that lack of any type of sexual education may lead to lower rates of condom use among adolescents. Statistically, adolescents who did not receive formal sex education were two times less likely to use a condom at sexual debut (Manlove, Ikramullah, & Terry-Humen, 2008; Committee on Adolescence, 2013). Poor timing of parental sex discussions has been associated with lower rates of safer sex protection. Maternal discussions about condom use prior to an adolescent's first sexual encounter may lead to a higher likelihood of prolonged condom use, but sex discussions that occur after sexual debut did not prove to be significant (Millier, Levin, Whitaker, & Xu, 1998). This finding implies the importance in the timing of safe sex talks between parents and their children. Discussing sex is considered a private matter in the United States, and adolescents report that sex is the topic most avoided with their parents. Mothers who are not confident in their knowledge of sexuality and STDs communicate less effectively about condom use (Committee on Adolescence, 2013). Often adolescents feel that their parents will look down on them for discussing sexual matters. Some parents feel that they do not have the skill set to discuss such issues with their children and tend to shy away from this type of conversation (Afifi, Joseph, & Aldeis, 2008).

Commented [A29]: Will this go on the table?

Commented [A30]: So does not using condoms mean no protection?

Commented [A31]: Was the alternative no protection?

Commented [A32]: I feel like you have moved into interpreting the findings, which doesn't belong here.

Discussion

Commented [A33]: Don't forget to summarize your findings, and speak of strengths and weaknesses of the studies you analyzed.

Theory

Commented [A34]: Please use subheadings for each of the theories.

There are various external predictors that may lead adolescents to proper safe sex practices, but in cases of consensual sex adolescents still have the power to decide whether or not

to use protection. Ultimately, the adolescent chooses whether or not to practice safe sex. Various theories may help to better understand the reasons behind an adolescent's decision to engage in safer sex. Condom use is a cognitive decision and adolescents must be aware of the risks of pregnancy and STDs associated with unprotected sex (Chambers & Rew, 2003). Adolescents are all individuals facing a multitude of issues and circumstances. Many theories may be applied to help understand an adolescent's decision to use or continue using protection. Because of the distinct differences that range across the adolescent population, no one theory could definitively describe an adolescent's decision-making process. It is prudent to explore various theories in order to appreciate why an adolescent chooses to practice safe sex (Chambers & Rew, 2003).

Commented [A35]: Good segway! But add the other stuff about the external predictors before this.

The Conflict Theory of Decision Making offers an interesting perspective on an adolescent's decision to use condoms. Created by Janis and Mann in 1977, the Conflict Theory of Decision Making states making a decision consists of "choice, commitment, and conflict…and the potential for loss" (Chambers & Rew, 2003). Vigilant decision making is an important component of the Conflict Theory of Decision Making since the practice of safe sex is achieved through a chain of various decisions. Those who engage in vigilant decision making are able to process information thoroughly. Unfortunately, adolescents often make sexual decisions based on emotion and may not fully process the risks of unprotected sex. As stated earlier, the Conflict Theory of Decision Making encompasses the "potential for loss." Fear of loss can often misguide an adolescent when deciding whether or not to use a condom, particularly in females. For example, if a female is afraid that she will lose her partner because of her desire to use a condom, she may decide to forgo condom use to please her partner (Chambers & Rew, 2003). On the other hand, a female who fears the social stigma of

adolescent pregnancy and STDs may engage in more vigilant decision making. A female with this mindset may view such consequences of unprotected sex as a potential loss. These losses can encompass missed education and unachieved future career goals (Chambers & Rew, 2003). Adolescents worried about self-image in this way, may have a higher level of decision esteem. According to the Conflict Theory of Decision Making, decision esteem is associated with more vigilant decision-making (Chambers & Rew, 2003). Adolescents with future concerns may be more likely to undergo a more rigorous decision making process in which he/she will take future risks into account before deciding on an action.

Another theory to explain and understand the decision to use a condom among the adolescent population is the Transtheoretical Model (TTM). Originally developed by Prochaska and DiClemente to understand smoking cessation, TTM has been applied to an array of health problems. TTM focuses on an individual's readiness to change through six steps: pre-contemplation, contemplation, preparation, action, maintenance, and termination. (Noar, Morokoff, & Redding, 2001). The stages focus on the time frame for which the individual is willing to change. An individual in the pre-contemplation stage is not willing to change within the next six months. When in the contemplation stage, the individual has intention to change in the next 6 months. Preparation means that the individual intends to change within the next 30 days, whereas action shows that the individual has made a specific change to his/her behavior within the last six months. Maintenance is defined by the individual's attempt to prevent relapse. Once the individual reaches the final stage of termination, he or she is no longer at a risk for relapse. In this stage, temptation is no longer an issue as it was in the maintenance stage. Upon reaching termination, the individual is confident in his/her ability to maintain a healthy lifestyle (Noar et al., 2001; Prochaska, 2008).

Self-efficacy is also an important construct of the Transtheoretical Model, especially when used to study condom use in adolescents. Self-efficacy relates to an individual's perceived ability to carry out a behavior, in this case, properly using a condom. Studies have indicated that those with higher self-efficacy are more persistent when attempting to achieve their desired outcome (French & Holland, 2013;(Noar et al., 2001)). Having high self-efficacy for condom use is important for female adolescents to be able to negotiate condom use with partners. Research shows that women are more likely to negotiate condom use than males. Varying research has shown that higher self-efficacy in condom use is associated with higher rates of condom use. French and Holland's study reported that those with higher condom use self-efficacy were more likely to directly request their partner to use a condom, whereas those with lower self-efficacy for condom use were less likely to require their partner to use a condom (2013).

Condom Negotiation

As stated above, a sense of self-efficacy leads to a greater ability to successfully negotiate condom use. The who possess the ability to reject (Self-efficacy) sex without a condom are more confident in their ability to negotiate condom use and to negotiate with partners who are unwilling to use a condom (French & Holland, 2013). While self-efficacy is an internal belief, condom negotiation is an actual behavioral skill and is considered one of the best predictors of condom use. Condom negotiation can be accomplished in a variety of strategies- direct, indirect, verbal, and non-verbal (French & Holland, 2013). Negotiation can include withholding sex or directly requesting a partner to use a condom, both of which have proven effective in increasing condom use. Communication is an important part of condom negotiation (French & Holland, 2013).

Condom negotiation is a particularly important skill for females. Males and females tend to have different beliefs regarding advantages of condoms (Calsyn et al., 2013). Female adolescents have reported lower condom use because they expect their partners to have negative attitudes towards condoms (Staras et al., 2013). Men are more likely to portray condoms negatively (Calsyn et al., 2013). Males often state that condoms reduce their sexual pleasure, do not fit properly, and interrupt the mood (Calsyn et al., 2013; De Visser, 2004). Unfortunately, many males and females still consider that it is the male's role to decide whether to use a condom. This attitude affirms older cultural beliefs that females should be passive in sexual matters (French & Holland, 2013).

Adolescents attending schools with condom availability programs are more likely to use condoms than students who attend schools without condom availability. Unfortunately research shows that female adolescents are generally unaffected by condom availability programs. Females may be less likely to request a condom from school and may be more timid about requiring a partner to wear a condom (Wretzel, Visintainer, & Pinkston Koenigs, 2011).

When parents communicate openly with their children about sexual issues, these children are more likely to delay sexual initiation, have fewer partners, and practice safer sex (O'Sullivan, Meyer-Bahlburg, & Watkins, 2001). sexual matters (Afifi, Joseph, & Aldeis, 2008). Adolescents may benefit if parents brought up the matter first to encourage open discussion.

Commented [A36]: ?

Interestingly, many parents discuss the risks of sexual behavior such as HIV, STDs, and pregnancy, yet only one quarter of parents advise their children on where contraceptives can be obtained to prevent against said risks (Afifi, Joseph, & Aldeis, 2008). Research is often inconsistent as there is no standard to measure communication between children and their parents (O'Sullivan, Meyer-Bahlburg, & Watkins, 2007).

Commented [A37]: Didn't you already talk about this?

Okay, so at the end of the day, you have:

1. From Results: Demographic and social factors on contraceptive use, as described in the research literature

2. From Discussion: All kinds of theories about how to get people to do things

How to you propose applying these two things to get kids to do dual use? How would you use what you learned from #1 to your advantage? (hint: you know WHO to target at least, and also maybe HOW). This section should be full of sentences like, "Because findings from this review indicate that X, theory Y may be helpful in addressing [phenomenon Z]"…things like that. Be specific in applying results, not just standalone generalities like, "It's important to know how kids act so they can stop getting all those STD's they get".

Revision Tracking Sheet & Self-Assessment (REQUIRED with every submission)

Name: Submission date: 1026/14 For return by: 11/11/14

X I affirm that all changes from the previous draft have been HIGHLIGHTED

Revision Tracking Sheet		
Date	Version	Overview of changes from last version
10/26/14	Version 2	• Updated corrections from recommendations • Added table based on findings • Added findings for first two "buckets"
9/16/14	Version 1	• Reorganized to fit required format • Removed information that is no longer relevant • Set up structure for findings.

Notes to reviewer concerning THIS submission:

- Dr. Chu, I've updated the corrections. I also moved a lot of things around for a better flow.
- I still have to add my findings for the final two buckets and work on my discussion and summary/recommendations.
- Is my intro hitting the inverted triangle mark? I'm afraid that I'm going from really wide to really narrow too quickly.
- I added the table based on your suggestions. Do I have to summarize each of my articles in the table? For example, give the author and which portion of the findings the study is related to? Or is the table okay as it is?

SELF-ASSESSMENT OF CURRENT DRAFT	
Writing issues	Self-Assessment: Unless marked OPTIONAL, you must provide text for EACH element
• Excessive spelling, punctuation, grammar, incomplete sentences, or writing issues.	Reviewed. Will be doing a more intensive proofread for next submission.
• References in APA format (both in text and in references section). Headings in APA format.	Yes.
• Formatting (double-spaced, 1" margins, page numbers, 12 point font, 0.5" paragraph indents).	Yes.
• Every paragraph must have a thesis statement; each statement in that paragraph should support that thesis statement.	I think this is better than previous submission.
• OTHER [OPTIONAL]	
Content	
Abstract (0.5-1 pg.) • 5 elements (Background, Problem/Thesis, Methodology, Findings/Results,	Will create abstract once research is complete.

Implications). Includes main thesis/argument/claim.	
Introduction (2-5 pgs.) • • □Inverted triangle • • □Properly cited definition • • □Statistical overview with relevant, detailed and correctly interpreted data	Added definition.
Methodology (1/2-1pg.) • Sources, types • Limitations; • • □Inclusion/exclusion criteria • • □Total N	Done.
Findings or Results (10-15 pages) • • □Transition statement • • □Organized and labeled subheadings that have been explicitly referred to at beginning of section • • □Fully populated table of your findings, with a proper title that accurately describes content and indicates total number of studies/articles represented, and properly labeled columns	Table added
Discussion (3-15 pgs.) • • □Short review of lit review findings • • □Analysis of strengths and weaknesses of issues raised • • □Critical examination of the issues raised in the literature	N/A
Summary and Recommendations (2-3 pgs.) • Concrete and well-informed recommendations that logically connect with results	N/A
References (3-20 pgs.) • Reputable sources only; all sources listed in paper are in references and vice versa; 3-20 pgs.	Yes
OTHER [OPTIONAL]	
Intellectual Rigor	
• Comprehensive: Is the literature review comprehensive and appropriate for the topic of the paper, with an accurate description and assessment of all relevant research?	Sources are appropriate, but might not be comprehensive as of yet.
• Synthesized: Is the literature adequately synthesized (i.e., appropriate level	Yes.

of meta- analysis applied, rather than reading like a "book report")?	
• Well-reasoned: Is the reasoning, explanations of opinions, conclusions and conceptualizations presented sound and well-supported by the evidence presented, or the opinions of authorities cited?	Yes. Will add more for discussion and summary
• Knowledgeable: Does paper demonstrate adequate knowledge about the basic scientific theories, as well as the institutions, policies, and regulations, encompassed by the health topic?	Yes.
• OTHER [OPTIONAL]	

Racial Disparities in the Prevalence of Obstructive Sleep Apnea and its Relationship with Cardiovascular Disease Outcomes

"Racial Disparities in Obstructive Sleep Apnea risk and Cardiovascular Disease Severity: Research Proposal to National Institutes of Health (R03 Mechanism)"

Abstract

Obstructive sleep apnea (OSA) is an important public health issue. OSA is a common but often undiagnosed disorder, which, if left untreated can increase the risk of hypertension, stroke, and other cardiovascular disease (CVD). Untreated OSA also causes a huge burden on the economic and health care system due to increased health care utilization and associated comorbidities. OSA is characterized by disrupted sleep, disordered breathing and excessive daytime sleepiness which is associated with workplace injuries and reduced work performance. The issues associated with diagnosis, treatment and lack of adherence to OSA treatment remain a public health challenge. Existing literature indicates that the incidence and prevalence of obstructive sleep apnea are higher among blacks than whites, and blacks are less likely to adhere to recommended treatment compared with other racial/ethnic groups. Blacks also have higher rates of mortality due to cardiovascular disease and are disproportionately affected by severe sleep apnea than whites. Improved awareness and knowledge about OSA symptoms among high risk populations, such as blacks, timely identification of OSA symptoms and diagnosis, effective OSA treatment methods and interventions aimed at improving adherence to those methods can not only help to reduce the mortality and morbidity due to OSA but also result in reduced morbidity due to cardiovascular disease among high risk populations. A better understanding of

the role of confounding factors and barriers to treatment for OSA could improve the implementation of treatment strategies and also reduce the social impact of obstructive sleep apnea.

Racial Disparities in the Prevalence of Obstructive Sleep Apnea and its Relationship with Cardiovascular Disease Outcomes

Obstructive sleep apnea is a chronic disorder which is characterized by one or more pauses in breathing while sleeping and causes disordered sleep (Gupta & Knapp, 2014). Each pause in breathing is called apnea and can last from a few seconds to a few minutes. These pauses in breathing leads to a poor quality sleep and thus excessive daytime sleepiness and tiredness (National Heart, Lung and Blood Institute, 2012). Sleep disordered breathing and associated symptoms such as sleep apnea not only affects the quality of life, but also increases the risk for various health conditions. Sleep apnea is of three types; Obstructive Sleep Apnea (OSA), Central Sleep Apnea (CSA) and complex or mixed sleep apnea, which is a combination of obstructive and central sleep apnea (Morgenthaler, Kagramanov, Hanak & Decker, 2006). OSA is associated with increased risk for stroke and heart disease and excessive daytime sleepiness and is also linked to car and workplace accidents (Gupta & Knapp, 2014).

Obstructive sleep apnea is one of the most common sleep disorders that affects 2 - 4% of the adult population (Miljuš, Tihaček-Šojić, Milić-Lemić, & Andjelković, 2014). In OSA, the airway collapses or becomes blocked during sleep and thus, loud snoring is heard due to shallow breathing. In CSA, the breathing is paused for brief periods because the brain is unable to send

correct signals to breathing muscles (National Heart, Lung and Blood Institute, 2012). Snoring is usually not observed in CSA. Although, the effects of CSA on the body are similar to OSA such as shortness of breath, drop in blood oxygen level and increased blood pressure, CSA is less common and often occurs in people who have had a heart failure (Leung & Bradly, 2001).

OSA has been linked as an independent risk factor for hypertension, stroke, and abnormal glucose metabolism and may contribute to cardiovascular morbidity (Gupta & Knapp, 2014). If left untreated, sleep apnea can also increase the risk for diabetes and obesity. Existing literature indicates that racial differences in sleep related problems such as insufficient sleep, sleep apnea, and disordered sleep might be related to the differences in outcomes of cardiovascular disease, hypertension and stroke (Kingsbury, Buxton, Emmons, & Redline, 2013).

OSA often goes undiagnosed because patients are often unaware of the symptoms and it cannot be detected through regular doctor visits. The person experiences excessive daytime sleepiness, morning headaches and fatigue or the symptoms are observed by the bed partner of the patient, such as loud snoring, snorting, gasping or episodes of apneas. The most commonly used treatment for sleep apnea is continuous positive airway pressure (CPAP) which includes a device that consists of a mask worn on the face which is connected with a plastic tube to a flow generator.

CPAP ensures a continuous flow of air during sleep and thus improves the sleep quality. Sleep apnea is strongly associated with increased blood pressure and risk of stroke. The relationship between obstructive sleep apnea and cardiovascular disease is synergistic and is highly correlated. A high prevalence of OSA was found among patients with coronary heart disease, arrhythmia and myocardial infarction (Shahar, Whitney & Redline, 2001). Some of the strongest risk factors for OSA are obesity and age older than 65 years (Collazo, 2014). Obesity

could increase the likelihood of airway collapse by directly affecting the upper airway tract, as fat is deposited in the surrounding structures. Being male is also one of the risk factors of OSA. Since men gain more weight centrally than women, the deposited fat pressurizes the upper airway tract, thus causing difficulty in breathing while sleeping. Males also have a higher prevalence of OSA and require higher continuous positive airway pressure (CPAP) for the treatment (Jordan, McSharry, & Malhotra, 2014).

Age is also another major risk factor for sleep apnea. The efficiency of the upper airway muscles decreases with age and thus older population may experience more apnea episodes and disordered sleep. Women of all ages have less severe apnea than men. There are racial/ethnic differences in prevalence of sleep apnea, but socioeconomic factors, living in disadvantaged neighborhoods, obesity and other existing health conditions may contribute to variations in sleep apnea prevalence (Ralls & Grigg-Damberger, 2012). A strong racial disparity exists in the prevalence and treatment of hypertension and its relationship to obstructive sleep apnea. African-Americans have shown to have severe sleep disordered breathing with a relative risk twofold as great as that for Caucasians independent of age, sex, and body mass index (Ancoli-Israel, 1995). Latino/ Hispanics also showed a higher prevalence of cardiovascular disease and increased risk of sleep disordered breathing as compared to Caucasians (Redline et al, 2014).

The purpose of this paper is to study the prevalence of obstructive sleep apnea, existing disparities in the prevalence of OSA among various racial groups, study the relevance of OSA in people who already have cardiovascular disease or are at risk of having cardiovascular disease and to understand the interactions between OSA, race, cardiovascular disease and other confounding variables such as socioeconomic status, age, obesity and education. There are several considerations in addressing the issues related to OSA and cardiovascular disease. The

complexity of the relationship between sleep apnea and comorbidities such as obesity and other metabolic disorders poses a serious challenge in addressing the problem. Obesity has shown to have a close synergistic relationship with sleep apnea. Other confounding factors that affect the prevalence of sleep apnea are diabetes and cardiovascular disease which are often present in patients with OSA and conversely, OSA has shown to exacerbate obesity and diabetes. Racial differences in prevalence rates and mortality rates due to CVD in patients with sleep apnea have also been reported in various studies. Patients with OSA place a significant burden on the healthcare system, especially because it often goes undiagnosed and has many associated health implications that increases morbidity. This paper is focused on presenting evidence from the literature to understand the possible interactions between obstructive sleep apnea, cardiovascular disease and race along with the role of confounding factors such as socioeconomic factors, diet & lifestyle factors and how identifying these risk factors could potentially reduce morbidity due to cardiovascular disease.

Review of Literature

Economic burden of OSA

The health care burden of morbidity due to sleep apnea and related health conditions is huge. It is estimated that sleep apnea is responsible for over 38,000 cardiovascular deaths yearly, with an associated 42 million dollar health care expenditure related to hospitalizations (William et al, 2014). Race, low socioeconomic status, low education, cost of OSA treatment and cost of sleep apnea comorbidity affects the healthcare costs. It was reported that the costs of untreated obstructive sleep apnea may double the medical and healthcare expenses primarily because of associated risks of CVD (Tarasiuk & Reuveni, 2013). OSA contributes to health care costs not only due to direct costs associated with management and treatment of OSA and the associated

medical conditions but also due to indirect expenses from low productivity at work linked with excessive daytime sleepiness which is one of the main symptoms of OSA, motor vehicle accidents, work place injuries and costs from poor life quality due to morbidity. A study by Sassani et al. indicated that vehicle collisions and fatalities in collisions due to sleep apnea alone contributed to 810,000 collisions and 1400 fatalities with an estimated 15.9 billion dollars of expenditure (Sassani et al., 2004).

Race and OSA

Racial disparities in various health issues and disease outcomes have been a challenge to public health. Health disparities exist among various ethnic/racial groups and disproportionately affects certain groups than another. African-Americans and other ethnic/racial minority groups are more likely to have unhealthy sleeping pattern that may contribute to disparities in health outcomes. Sleep apnea occurs more frequently among African-Americans and Asians than Caucasians and has been significantly associated with hypertension, obesity and diabetes mellitus (Leung & Bradly, 2001). Lauderdale et al. found that African-Americans have lower mean sleep duration, lower sleep efficiency, and higher sleep latency as compared to their white counterparts, even after controlling for various socioeconomic and demographic factors (Lauderdale et al, 2006).

Black people younger than 25 years and older than 65 years have a higher prevalence of OSA than people from other racial groups (Olafiranye, Akinboboye, Mitchell, Ogedegbe, & Jean-Louis, 2013). A study done by the Chicago section of the Coronary Artery Risk Development in Young Adults project reported that Black men slept 82 minutes less per night on average as compared to the group with the best overall sleep characteristics (White women)

even after controlling for social status, various comorbidities, body mass index, and sleep-disordered breathing (Bryson & Edwards,2013).

A population-based survey conducted by Kripke et al. estimated that 16.3% of the US Hispanics and racial minorities have Obstructive Sleep Apnea Syndrome (OSAS) or OSA as compared with 4.9% of non-Hispanic whites aged 40 to 64 years. The findings from the study revealed that the subgroup of non-Hispanic, non- black minorities, who were mostly Asians, might have a higher prevalence of OSA as compared with Hispanics and blacks (Kripke et al, 1997). Another study has also suggested that Asians with OSA have a greater severity of illness compared with whites. Craniofacial anatomy is a well-known risk factor for the development of OSA and the variations in craniofacial anatomy are attributed to race. A prospective study was done among Far-East Asian men (Chinese, Japanese and Korean) and white men to study the difference in OSA prevalence. The study suggested that despite low BMI and after controlling for age, the Far-East Asian men had severe OSA syndrome than whites. Therefore, obesity or high BMI may be a less important risk factor for OSA in Asians as opposed to other racial/ethnic groups such as African-Americans where BMI is a significant indicator of OSA risk (Leung & Bradly, 2001).

A study by Friedman et al. was done to study the relative incidence of obstructive sleep apnea-hypopnea syndrome (OSAHS) in the African-Americans as compared to Caucasian-Americans. It was found that OSAHS and loud snoring was more common in African Americans than Caucasian Americans. Since loud snoring is one of the signs of sleep apnea that could help to diagnose sleep apnea timely, it was reported that African Americans accepted snoring as normal and that might have contributed to late detection of sleep apnea among this racial group (Friedman et al, 2006).

Existing literature also indicates that racial differences in sleep related problems such as insufficient sleep, sleep apnea, and disordered sleep might be related to the racial differences in outcomes of cardiovascular disease, hypertension and stroke (Kingsbury, Buxton, Emmons, & Redline, 2013).

Cardiovascular disease and OSA

Sleep-related breathing disorders are highly prevalent in people with a history of cardiovascular disease (Shamsuzzaman, Gersh & Somers, 2003). Of all the sleep-related disorders, Obstructive sleep apnea (OSA) is most common and affects approximately 15 million adult Americans, the majority of them having an established history of hypertension, stroke and atrial fibrillation. OSA affects approximately 50% of the patients with cardiovascular disease. Several studies have indicated that patients with stroke have a higher incidence of obstructive sleep apnea as compared to people without stroke independent of sex and age (Dyken, Somers, Yamada, Ren & Zimmerman, 1996). For several years, the link between cardiovascular disease and sleep apnea was thought to be a result of various factors such as age, sex and BMI (Body Mass Index). Until recently, various epidemiological studies showed sleep-related breathing disorders to be an independent risk factor for hypertension and cardiac arrhythmia. A causal role of OSA in the development of cardiovascular disease is supported by the evidence that any form of sleep apnea contributes to increased blood pressure, intermittent hypoxia, or oxygen deprivation and sleep fragmentation (Kendzerska, Gershon, Hawker, Leung & Tomlinson, 2014).

Several studies have shown a disproportionately high prevalence of hypertension and more severe sleep apnea in African-Americans than Caucasians, associating OSA to be a major risk factor in causing possible differences in morbidity and mortality due to hypertension (Sands,

Botros, Lichtman, & Yaggi, 2008). Despite recent decline, cardiovascular disease still remains the leading cause of death in African-American and Caucasians in the United States. The decline is less accountable for African-Americans because of a disproportionately high burden of mortality due to heart disease and low life expectancy rates (Roger et al., 2012). A population-based study was carried out to study sleep apnea as a risk factor for hypertension and it was found that the difference in blood pressure while sleeping varied significantly from the blood pressure during other times of the day among people with obstructive sleep apnea (Young et al, 1997).

The prevalence rate of hypertension among African-Americans is twice that in Caucasians (Go et al, 2013). Several studies have documented a high prevalence of OSA in patients with heart failure. Conversely, a causal role of OSA in the progression of heart failure is also suggested and the treatment of OSA significantly improved the cardiac function in patients with OSA (Gottlieb et al, 2010). The findings were consistent with another study that showed that a greater prevalence of severe sleep apnea among African-Americans and similarly high levels of blood pressure was also observed and treating sleep apnea reduced the incidence of hypertension (Sands, Botros, Lichtman, & Yaggi, 2008).

CPAP therapy for OSA

The increased risk of hypertension associated with untreated sleep apnea was linked to long-term incidence of stroke and coronary heart disease and the use of CPAP may reduce the risk of hypertension and stroke (Campos-Rodriguez et al, 2014). Despite the evidence that continuous positive airway pressure (CPAP) is an effective method for treatment of OSA and can help to improve the quality of life, compliance with the use of CPAP therapy among certain racial groups, especially blacks, is low. CPAP treatment allows a continuous flow of air through

the airway passage which helps to control blood pressure spikes. CPAP method includes a device that consists of a mask worn on the face by the patient and the mask is connected to a plastic tube to a flow generator that ensures a continuous flow of air for proper breathing during sleep. Although a direct association between CPAP and reduced risk of stroke has not been established, regular use of CPAP to treat sleep apnea have shown to reduce daytime and nighttime hypertension thereby indirectly reducing the risk of stroke.

Becker et al concluded in their study that the use of CPAP showed a significant improvement in arterial blood pressure. After 9 weeks of CPAP treatment, there was a drop of 10 mm Hg in mean blood pressure, which could potentially reduce the risk of coronary heart disease by 37% and stroke risk by 56% (Becker et al, 2003). Also, CPAP helps to provide stable sleep and thus reduces the risk of daytime sleepiness and fatigue, which in turn has shown to reduce the risk of cardio metabolic disorders such as obesity and diabetes. People experience improved energy levels after the use of CPAP, are physically active and have improved productivity at work as compared to people with untreated sleep apnea who battle with excessive fatigue, headache and sleepiness (Montserrat, 2001).

Workplace accidents and OSA

Sleep-disordered breathing poses health risks, risks of occupational accidents and low work performance. People who have sleep apnea have a three- to seven fold increased risk of motor vehicle accidents (Tarasiuk & Reuveni, 2013). A study was done to compare the rates of occupational injuries among patients suffering from sleep-disordered breathing with an employed, age-matched random sample of the general population. It was found that the risk of being involved in occupational accidents was twofold for males and threefold for females as compared to the general population (Ulfberg, Carter & Edling, 2000). Similar findings were

reported in another study that showed that drivers who had large neck size, which is used to measure total score in the sleep apnea questionnaire and had a history of sleep apnea or disordered sleep were at greater risks of car accidents due to troubled sleep and daytime sleepiness (Amra et.al, 2012).

OSA and confounding factors

The association between disadvantaged neighborhood, residential environment and poor health outcomes is well established. Several biological and psychosocial factors such as age, socioeconomic status, diet and mental health could potentially be mediating the differences in prevalence of hypertension among various racial groups and the difference in health outcomes among various racial groups.

The sleep duration is affected by socioeconomic factors, segregation, neighborhood environment and lifestyle differences (Hale & Phuong Do, 2007). These confounding factors may result in inadequate sleep due to the presence of psychosocial stressors among racial minority groups and residents of urban environments. Low income and low educational level of people from ethnic/ racial minority groups could probably be contributing to the stress due to night work shifts and working more than one job and thus reduced sleep duration. Racial, economic and social segregation affects the health of the residents and disproportionately exposes them to health risks. Residence in an inner city was associated with increased risk of disordered sleeping as compared to non-urban areas. Among the four racial/ethnic groups, White, Black, Mexican American, other Hispanics and other Non-Hispanics, blacks and other Hispanics showed a high prevalence of living in the inner city which was linked to the increased risks of sleep related disorders and thus poor health outcomes (Hale & Phuong Do, 2007). Apart from demographic, socioeconomic and environment factors that contribute to poor health

outcomes, existing health conditions among different racial groups and disparities in access and utilization of health care plays a significant role in the prevalence of OSA.

Barriers to OSA identification and treatment

Low education and awareness levels about obstructive sleep apnea among people, especially among blacks, was considered to be one of the major factors that results in under diagnosis, late diagnosis and lack of timely treatment for OSA (Rosen, Zozula, Jahn & Carsond, 2001). Apart from lack of awareness about the symptoms of OSA and about treatments available for OSA, low compliance with the OSA treatment methods among the patients was another barrier contributes to the increased prevalence of OSA. Several studies have reported a significant role of beliefs and knowledge on understanding and reporting of sleep-related disorders among the blacks. It was found that misconceptions about sleep apnea and lack of knowledge about sleep apnea symptoms were significantly related to poor diagnosis and treatment of sleep apnea (Rosen, Zozula, Jahn & Carsond, 2001).

A study conducted by Friedman et al., showed that 33% of the black participants considered snoring to be normal as compared with 20% of the white participants. Bed partners of the participants of black race/ethnicity were also more likely to accept loud snoring as normal. Overall awareness about possible risk factors or signs of sleep apnea was lower among participants from the black racial group (Friedman et al, 2006). Moreover, lower acceptance rates for the CPAP treatment of sleep apnea was demonstrated due to the inconvenience and misconceptions about the device. Participants were more likely to refuse the treatment for sleep apnea due to insufficient knowledge about the CPAP machine, discomfort in wearing the mask while sleeping and concerns about their partners' acceptance of the mask while sleeping with them. Thus, low rates of adherence to the treatment were shown to be a contributing factor to the

high prevalence and morbidity due to sleep apnea (Shaw et al., 2012). The use of this therapy has shown a significant improvement in sleep and breathing during sleep, thus reducing daytime sleepiness. CPAP has also shown to reduce the risks of stroke and hypertension among the patients (Salepci et al., 2013). Sleep apnea treatment requires long-term management and adherence. The challenges faced in administering CPAP include the cost-effectiveness, time availability because the patient has to spend the night at the sleep clinic for the treatment and most importantly adherence to CPAP treatment.

Despite of clinical and medical advancements, existing data suggest that 82% of men and 93% of women with sleep apnea in the United States remain undiagnosed (William et al, 2014). The inability to diagnose OSA timely and high rates of undiagnosed cases are attributed to the inability of people to identify their symptoms and report disordered sleep to the doctor. The symptoms are often identified by the family members or bed partners of the patients, but are misdiagnosed as insomnia or regular snoring. Thus, patient awareness and knowledge of symptoms plays a crucial role in reducing the morbidity due to OSA through timely treatment. Since morbidity and mortality due to OSA are largely due to late detection, it calls for interventions targeted towards increasing awareness about signs and symptoms of sleep apnea to help in the timely and accurate identification of sleep-related disorders. Such interventions will not only ensure a timely treatment of sleep apnea, but will also help in detecting risks for comorbidities such as hypertension, stroke and cardiovascular disease. Race, socioeconomic factors, education, neighborhood environments, obesity and age have shown to be the major risk factors for sleep apnea prevalence and controlling for one may potentially control the risk of sleep apnea. Polysomnography is one of the best methods to test for OSA but it is expensive, cumbersome and time-consuming (Jordan, McSharry & Malhotra, 2014). There is a need for

more efficient and cost effective diagnosis and management techniques for sleep apnea. Home diagnosis has been hypothesized to be helpful in managing sleep apnea, but lack of evidence suggests that it is being investigated or no conclusive studies have been reported. On the other hand, CPAP is a cost-effective treatment, but requires long-term adherence. People should be made aware about the CPAP treatment therapy and be given information about the treatment to make them more receptive and overcome any misconceptions associated with using the device and adhering to the treatment. Therefore, it is imperative to focus more research studies on identifying risks of sleep related disorders such as sleep apnea among certain racial groups, which may help in developing interventions to reduce the risk factors of sleep apnea and thus potentially reduce cardiovascular disease risk and morbidity among high risk racial groups.

Gaps and Issues in the Literature

Obstructive sleep apnea (OSA) is a common disorder that affects people of all ages, but is more prevalent among older adults (Miljuš, Tihaček-Šojić, Milić-Lemić, & Andjelković, 2014). Poor sleep quality, excessive daytime sleepiness and fatigue are the most common symptoms of sleep apnea, although many patients may be asymptomatic. Although a vast majority of studies has shown that OSA and cardiovascular disease are intertwined, little is known about the exact mechanics of the relationship. The data on long term treatment of sleep apnea and its outcome is also scarce and does not provide conclusive evidence. The studies done on racial differences in sleep apnea prevalence have provided data mainly among two racial groups; Blacks and Caucasians. Very limited data were available on sleep apnea risks among other racial groups. It is important to understand the existing gaps in sleep apnea research and how addressing those gaps can improve sleep apnea identification and treatment and the quality of life by reducing the

risk of comorbidities associated with sleep apnea. Below are some of the gaps in research that needs to be studied and provide conclusive evidence for OSA prevalence and treatments.

Sleep apnea and Race

The majority of the available data on sleep apnea and racial disparities has shown a difference in the prevalence of sleep apnea among blacks and Caucasians. A strong racial disparity exists in the prevalence and treatment of hypertension and its relationship to sleep apnea. African-Americans are two times more likely to have severe sleep disordered breathing than Caucasians (Ancoli-Israel, 1995). Latino/Hispanics also showed a higher prevalence of cardiovascular disease and increased risk of sleep disordered breathing as compared to Caucasians (Redline et al, 2014). Although studies suggest a strong link between race and sleep apnea, very limited research has been done in other racial/ethnic groups to study the prevalence and severity of sleep apnea. Since socioeconomic status, neighborhood environment, education level and lifestyle factors play a confounding role in the health and health-related outcomes of minority groups, research on other racial and minority groups would help to study the underlying factors that brings about differences in sleep apnea prevalence and have a comparative evidence to study if there is a direct link between race and sleep apnea.

Patient adherence to treatments

The most commonly used treatment for moderate to severe sleep apnea is continuous positive airway pressure (CPAP). Other treatment options include surgical correction of upper airway and mouth pieces (also known as oral appliances). The commonly used methods for diagnosing and treating OSA are cumbersome, resource intensive, and often inconvenient for the patient. Low acceptance rates for the CPAP treatment of sleep apnea has been reported as a

major factor in the undiagnosed and untreated cases of sleep apnea. The low acceptance of CPAP method is due to the inconvenience, discomfort and misconceptions associated with the device. Studies have shown that patients are more likely to refuse the treatment for sleep apnea due to insufficient knowledge about the CPAP machine, discomfort in wearing the mask while sleeping, excessive salivation, nasal and oral dryness and concerns about their partners' acceptance of the mask while sleeping with them (Eisenberg, 2007). Thus, low rates of adherence to the treatment were shown to be a contributing factor to the high prevalence and morbidity due to sleep apnea (Shaw et al., 2012). The limited evidence of comparative research between CPAP and other available options for effective treatment and management of sleep apnea indicates an existing gap in research. Compliance remains a barrier to CPAP treatment, but there is insufficient evidence to evaluate compliance with other treatment options.

Long term clinical outcomes

Treatment of sleep apnea requires long term management and adherence to the treatment methods along with lifestyle changes such as weight reduction. The existing literature provides inadequate data on the long-term clinical outcomes of using CPAP and other methods for treatment of sleep apnea and how it helps to reduce morbidities related to heart disease, hypertension and metabolic disorders such as diabetes and obesity. The studies done in the past have focused on intermediate measures based on sleep testing scores, Apnea-Hypopnea Index (AHI) and not on the evaluation of long term clinical outcomes. Research focused on studying the impact of long-term clinical outcomes of treatment methods would help to determine the effectiveness of treatments and how those treatments can eventually help in reducing mortality and morbidity due to cardiovascular disease (including stroke, coronary artery disease, congestive heart failure, and atrial fibrillation), and diabetes.

Cost-effectiveness

Studies about cost-effectiveness of different treatment methods and management strategies for sleep apnea are very limited. Most data is available on CPAP method and how it is used more often than other methods, but not how cost-effective CPAP is when compared to other available treatments. The cost of treatment plays an important role in patient's adherence to sleep apnea therapy and effective outcomes. A comparative cost analysis, among different methods based on the scale of cost per treatment, utilization, benefits, clinical outcomes, and effectiveness of the methods would help to distinguish between the cost-effectiveness of the treatments and thus help in planning and targeting interventions towards low-income and minority groups and in the community in general.

Interventions that can improve compliance with CPAP, oral device, and other treatments

It is important to find ways to improve compliance with sleep apnea treatment. Lack of awareness about the available treatment methods, knowledge of CPAP device and misconceptions were reported to be responsible for low compliance. There is little evidence that suggests that the measures to address low compliance with CPAP treatment and other treatment options are undertaken or if there are any specific adjunct interventions which may improve CPAP compliance. Interventions aimed at providing intensive patient education, training, creating awareness in the community, support groups and behavioral therapy can help to improve compliance (Patel et al, 2013).

Discussion

Sleep apnea is a serious condition that greatly affects the quality of life and if left untreated, can result in mortality and morbidity due to associated cardiovascular risks. It is important to study

why certain racial groups are more affected than other groups and why communities are burdened disproportionately from sleep apnea. It is crucial to study what role does race/ethnicity of an individual play in predisposing people to sleep apnea. Although sociodemographic, environmental, economic, educational and cultural factors contribute to the prevalence of this disease, it would be helpful to study how race alone is a significant factor in the sleep apnea prevalence and morbidity.

The availability of various treatment options for sleep apnea, yet low treatment rates among points towards gaps in the health care system and low awareness levels among the community members. An increased awareness about screening methods, home-testing, identifying risk factors such as excessive snoring and improving adherence to treatment can result in better health outcomes for people with sleep apnea.

Effective behavioral interventions are needed to increase the number of high-risk population receiving adequate OSA assessment and treatment. There is a need for interventions aimed at improving behaviors of the people that includes reducing behaviors that predisposes them to be at risk of sleep apnea and encouraging healthy behaviors that helps them identify symptoms and risks of sleep apnea timely, thus reducing morbidity due to sleep apnea through early detection and alternatively reduce cardiovascular morbidity. Risk-reducing behaviors could include healthy diet and lifestyle changes to reduce obesity, diabetes mellitus and hypertension that are directly associated with sleep apnea.

APPENDIX A

Racial Disparities in Obstructive Sleep Apnea (OSA) and Cardiovascular Disease Severity:

Research Proposal to National Institutes of Health (R03 Mechanism)

Racial Disparities in Obstructive Sleep Apnea (OSA) and Cardiovascular Disease Severity: Research Proposal to National Institutes of Health (R03 Mechanism)

ABSTRACT

The purpose of this R03 proposal is to understand the correlation between Obstructive Sleep Apnea (OSA) risk and cardiovascular disease (CVD) severity among various racial/ethnic groups in New York City. This study will also help to identify the relationship between race, education level and other sociodemograpic factors and the risk of OSA among the sample.

OSA is a common but often undiagnosed disorder, which, if left untreated can increase the risk of hypertension, stroke, and other cardiovascular disease (CVD). An estimated 15 million adult Americans are affected by OSA and is largely present in patients with hypertension and other cardiovascular disease. Untreated OSA also causes a huge burden on the economic and health care system due to increased health care utilization and associated comorbidities. OSA also increases the risk of workplace and car accidents due to excessive daytime sleepiness, fatigue and headaches.

Studies have shown that racial differences in sleep related problems such as insufficient sleep, sleep apnea, and disordered sleep might be related to the differences in outcomes of cardiovascular disease, hypertension and stroke. African-Americans and other ethnic/racial minority groups are more likely to have unhealthy sleeping pattern that may contribute to disparities in health outcomes. Existing literature also suggests that sleep apnea occurs more frequently among African-Americans than Caucasians and has been significantly associated with hypertension, obesity and diabetes mellitus. Although, the majority of literature suggests that racial/ethnic minority groups are more severely affected by OSA, very limited data are presented for racial groups such as Asians and Hispanics. The proposed research will focus on studying low-risk and high-risk groups for OSA, identify the rate of OSA in various racial/ethnic groups which have not been studied, and analyze its correlation to CVD severity.

I. SPECIFIC AIMS

Obstructive Sleep Apnea (OSA) is one of the most common sleep disorder affecting 2-4% of the adult population in the United States (Miljuš, Tihaček-Šojić, Milić-Lemić, & Andjelković, 2014). OSA is a chronic disorder which is characterized by one or more pauses in breathing while sleeping and causes disordered sleep (Qureshi, Ballard, & Nelson, 2003). OSA has been linked as an independent risk factor for hypertension (Kapa, Kuniyoshi, & Somers, 2008), stroke (Dyken, & Im, 2009), abnormal glucose metabolism (Parish, Adam, & Facchiano, 2007) and may contribute to cardiovascular morbidity (Gupta & Knapp, 2014). People with OSA have also been shown to have a three- to seven- fold increased risk of motor vehicle accidents (Tarasiuk & Reuveni, 2013). The health care burden of morbidity due to sleep apnea and related health conditions is huge. It is estimated that OSA is responsible for over 38,000 cardiovascular deaths yearly (Öğretmenoğlu et al., 2005), with an associated 42 million dollar health care expenditure related to hospitalizations (William et al., 2014). Over 40% of patients with mild OSA and 69% of patients with severe OSA have shown to have hypertension (Young et al., 2008). OSA treatment has shown to reduce the risk of cardiovascular disease (CVD) by 64% (Buchner, Sanner, Borgel, & Rump, 2007) that suggests a correlation between OSA risk and CVD.

Existing literature indicates that racial differences in sleep related problems such as insufficient sleep, sleep apnea, and disordered sleep might be related to the differences in outcomes of cardiovascular disease, hypertension and stroke (Kingsbury, Buxton, Emmons, & Redline, 2013). African-Americans have shown to have lower mean sleep duration, lower sleep efficiency, and higher sleep latency as compared to their white counterparts, even after controlling for various socioeconomic and demographic factors (Lauderdale et al., 2006). Although the majority of the data suggests that blacks are disproportionately affected by OSA, very limited data are available for other racial groups such as Asians and Hispanics that can provide any conclusive evidence about the role of race in OSA risk and CVD outcomes. Thus, this study will help to identify the rate of OSA in various racial/ethnic groups which have not been studied, and analyze its correlation to CVD severity.

In the proposed cross-sectional study, we will identify the correlation between OSA and cardiac disease severity among individuals from various racial/ethnic groups in New York City. The participants, will be aged $\geq$ 18 years, with a cardiovascular disease diagnosis, and will be selected from different primary care centers located in racially diverse neighborhoods in New York City. Each neighborhood will be selected based on the data from the US Census. A sample size of 240 participants will be recruited for the study from the following racial/ethnic groups: Whites, non-Hispanics; Black/African American, non-Hispanic; Asian, Hispanic. Surveys will be used to collect data and questionnaires such as the ARES Watermark Questionnaire and Berlin Questionnaire will be used to study sleep variables. Neck size measurement will be done using a measuring tape as large neck size is a risk factor for sleep apnea (Dixon, Schachter & O'Brien, 2003). The Epworth sleepiness scale will be used to measure the general level of daytime sleepiness which is the most common symptom of obstructive sleep apnea and questions about health, physical activity and history of heart disease will also be included in the survey about sociodemographic factors.

Aim 1: To study the correlation between OSA and cardiovascular disease severity in a sample of patients with CVD from various racial/ethnic groups living in New York City.

Aim 2: To describe the role of race, socioeconomic status and education level on OSA risk among the sample.

Impact: This study would help to determine the correlation between OSA risk and CVD severity in racial groups that are not previously well studied. It would also help to identify the role of race alone in the presence of OSA risk in CVD patients and how it adds to the burden of health disparities among various racial/ethnic groups. The findings from the study can help to postulate possible interventions and programs for the racially diverse communities and possibly reduce the risk and burden of morbidity and mortality due to CVD.

II. RESEARCH STRATEGY

1. Significance

1.1 Sleep health is one of the goals of Healthy People 2020: Sleep is an important determinant of health and well-being of an individual. The burden of sleep disorders and related comorbidities is huge. It is well established that if left untreated, sleep disorders increases the risk of heart disease, obesity, diabetes and high blood pressure. One of the goals of Healthy People 2020 concerning sleep health aims at encouraging people with excessive daytime sleepiness and other symptoms of OSA to seek medical assessment and care (U.S. Department of Health & Human Services [HHS], 2011). This study will help to identify the rate of risk of OSA among various racial groups and to contribute to the evidence base for interventions specific to different groups. The objectives of this study are consistent with the nation's goal to reduce health disparities among various racial groups and to improve population sleep health. The research is focused on studying the correlation between OSA and CVD and the findings from this study can form the basis for future interventions targeted at racial minority groups to improve identification of sleep disorders and help reduce the overall burden of heart diseases.

1.2. Rationale for focusing on people with CVD as the study population: The rationale for focusing on individuals with CVD as the target population for assessing the risk of OSA among them is twofold. Firstly, the existing literature has provided a strong synergistic link between OSA and heart diseases. Studies have shown that OSA affects approximately 50% of the patients with cardiovascular disease (Dyken, Somers, Yamada, Ren & Zimmerman, 1996). But it is not clear if OSA is a risk factor for CVD risk or presence of heart problems is a risk factor for OSA. Therefore, selecting the participants as those with established CVD history would help to determine the direction of the relationship between OSA and CVD. Secondly, certain races have shown to be at higher risk of heart disease such as blacks as compared to whites (Olafiranye, Akinboboye, Mitchell, Ogedegbe, & Jean-Louis, 2013) and other races (Leung & Bradly, 2001). Cardiovascular disease still remains the leading cause of death in African-American and Caucasians in the United States (Roger et al., 2012). Selecting participants with CVD will rule out the possibility of having an unequal number of participants representing different racial/ethnic groups and thus will help provide a better estimate of the rate of OSA risk in various racial groups.

1.3. OSA is largely under-diagnosed among Asians and Hispanics: Although race has shown to be a factor in causing disparities in sleep health, it is not certain if race alone plays a significant role in causing differences in prevalence of obstructive sleep apnea. Studies have shown a disproportionately high prevalence of hypertension and more severe sleep apnea in African-Americans than Caucasians (Sands, Botros, Lichtman, & Yaggi, 2008). Very limited data about OSA prevalence are available for Asians and Hispanics. Of the few studies done, the majority of them suggested a higher prevalence rate of OSA among Asians and Hispanics as compared to Caucasians (Redline et al., 2014), even after controlling for factors such as obesity (Leung & Bradly, 2001; Kripke et al., 1997). Selective sampling of the racial groups of interest will provide a better understanding about OSA severity for understudied populations. The symptoms of OSA are usually not identified or diagnosed correctly or in a timely manner by the patients. This increases the severity of the condition and thus poses added risks to health due to associated conditions such as heart diseases and diabetes. This research will provide data about the possible reasons for under-diagnosis of OSA in some racial groups, which can be used to design culturally and linguistically tailored programs for those groups or communities.

2. Innovation

Despite the identification of race/ethnicity as a risk factor for OSA, there is a paucity of data for various racial groups other than whites and blacks. This proposal will address this gap in the literature. This proposal is innovative for the following reasons.

2.1 Recruiting participants from multiple under-represented racial/ethnic groups: This study is one of the few that would focus on studying OSA among different racial groups, as the majority of existing data are with whites and blacks. A population-based survey estimated that, among those aged 40 to 64 years old, 16.3% of the Hispanics and racial minorities have OSA as compared with 4.9% of non-Hispanic whites (Kripke et al., 1997). Recruiting participants from multiple under-represented racial groups will help in analyzing the OSA risk specific to each group and role of confounding factors such as income, and education, and allow for between-group comparisons.

2.2 Patients with CVD as the study population: The study is innovative in its approach as it will recruit patients with CVD as the target population. The lack of conclusive data about the relationship between OSA and CVD from the past studies, possibly due to different sampling schemes and different techniques used for assessing risk for sleep disorders, may provide an altered picture about the true direction of the correlation between OSA and CVD. This study will assess the high-risk and low-risk groups for OSA in the community who has an established history of CVD.

3. Approach

3.1. Overview of Project

Obstructive sleep apnea (OSA) has shown to affect an estimated 20 million adult Americans and is a risk factor for hypertension and cardiovascular disorders (Aggarwal, Jan, Agarwal, & Tajik, 2015). Studies have shown that the incidence of OSA in patients with cardiovascular disease (CVD) is 30 to 50 percent (Tiengo, Fadini, & Avogaro, 2008; Torres-Alba et al., 2013).

The proposed project will study the correlation between Obstructive Sleep Apnea (OSA) risk and CVD severity among a sample of 240 people living in New York City. The participants for the study will be selected from 4 primary care centers in 4 different and racially diverse neighborhoods in New York City. The sample population will be individuals aged 18 years or older who have cardiovascular disease and self-identify as one or more of the following racial/ethnic groups: Whites, non-Hispanics; Black/ African Americans, non-Hispanics; Hispanic and Asian. OSA risk will be measured with the ARES (Apnea Risk Evaluation System) Watermark questionnaire (which includes the Epworth Sleepiness Scale) and the Berlin Questionnaire. These questionnaires will provide information on daytime sleepiness, hypertension, snoring and BMI, all of which are independent risk factors of OSA. Other surveys will be used to collect socioeconomic and demographic data. In addition to examining the relationship between OSA risk and CVD severity by racial/ethnic group, we will study if factors such as low awareness of OSA, lack of access to care, and low socioeconomic status play a role in the risk of sleep apnea among the sample, including how these factors vary by race/ ethnicity.

3.2. Recruitment of Participants

The participants for the study will be recruited from 4 different primary care centers in New York City. Based on the power analysis using G*Power calculation tool, we plan to collect data for 240 patients for an alpha of 0.05 and a power of 95%. Each primary care center will be selected from a racially diverse neighborhood based on the data from US Census 2010. 60 participants from each racial group will be recruited. Borough Park was shown to have a higher percentage of White, non-Hispanic population; Bedford–Stuyvesant has a high percentage of Black, non-Hispanic population; West Queens has a high Hispanic population and Flushing has high Asian, non-Hispanic population. One primary care center from each of these neighborhoods will be the recruitment sites for the participants. Each primary care center will recruit 80 participants. The inclusion criteria for the sample will be: age 18 years or older, self-identify as one or more of the racial/ethnic groups listed above, residents of that area, with no diagnosis of sleep apnea or any other sleep disorder, having CVD (such as hypertension, stroke, arrhythmia, heart attack etc.), be the only member of the family participating in the study and consent to participate. The exclusion criteria for the study are: having a history or diagnosis of sleep apnea or other sleep related disorder, being pregnant and impaired cognitive or functional ability.

3.3. Study procedures

3.3. a. Recruitment and sampling procedure

The participants for the study will be recruited at primary care centers. Teams of study recruiters will be assigned to various data collection sites. Based on the patient data from the physician, patients having a history or currently diagnosed as having CVD such as hypertension, stroke, heart failure, arrhythmia etc. will be selected to fill an eligibility form. The eligibility form will have questions related to the inclusion criteria such as age, race, CVD diagnosis and that would decide if the patient qualifies to be enrolled into the study. Surveys will be used to collect data and each participant will be paid $20 for their participation. All the surveys will have two copies of the consent form, one copy for the participant and other to be attached with the completed survey. Both copies of the consent form will be signed by the participants before filling the survey. A total of 60 participants will be recruited from each racial group and each primary care center.

3.3. b. Informed Consent

Participation in the proposed study will be completely voluntary. An IRB approved consent form will be attached to the survey. The participants will be required to read and sign the consent form before filling the survey. The consent form will include information about the study, the principal investigator, the goal of conducting the research study and criteria to be in the study as per the IRB rules for writing a consent form. The recruitment approach and data collection procedure will comply with the Health Insurance Portability and Accountability Act (HIPAA) laws that protect the privacy of patient's medical data and health information.

3.3. c. Quantitative Data Collection Procedures

The method used for data collection will be surveys. Along with surveys, neck measurement will be taken from each participant using a measuring tape which is required to complete scoring for OSA risk in the ARES Watermark Questionnaire.

3.3. d. Incentives

All the participants will be paid $20 for their participation. After completion of the survey, participants will be given an information packet containing information about sleep apnea, how to identify symptoms of sleep apnea and some information on resources available in their community (such as nearest sleep centers etc.).

3.4. Measures

The measures used for data collection are: The ARES Watermark Questionnaire which includes the Epworth Sleepiness Scale, the Berlin Questionnaire and survey questions about demographics and socioeconomic status. To study the severity of CVD among the patients, having a history or current diagnosis of two or more CVD will be studied among the sample.

The Apnea Risk Evaluation System (ARES™) Questionnaire will be used to identify people at risk of OSA. The questionnaire includes demographic and anthropometric data, diseases associated with OSA risk (i.e. History of stroke, hypertension, diabetes or any heart disease) or history of sleep apnea, the Epworth Sleepiness Scale, and frequency rating for snoring, waking up choking and witnessed apneas. The Epworth Sleepiness Scale included in the ARES questionnaire is an eight-item questionnaire that measures daytime sleepiness which is one of the most common symptoms of sleep apnea. The ARES Questionnaire provides a score that decides the level of OSA risk among the patient. A score of 4 or 5 is considered "low-risk", a score of 6 to 10 is "high risk" and a score of 11 or more shows a "very high risk" for OSA. A study validating the ARES questionnaire has shown that ARES has a sensitivity of 0.94, specificity of 0.79, positive predictive value of 0.91 and negative predictive value of 0.86 (Levendowski et al., 2007).

The Berlin questionnaire is an 11-item questionnaire that includes questions about risk factors for sleep apnea, including snoring behavior, fatigue, and obesity or hypertension. The Berlin questionnaire is a validated instrument that is used to identify individuals who are at risk for OSA in primary and some non-primary care settings. Based on scoring for each question in each of the three categories, the patient is considered to be at high risk if two or more categories are positive (i.e. A score of 2 or more) and low risk if only one or no category is positive. The questionnaire was validated by Chung et al. in 2008 (Chung et. al, 2008).

The dependent variable for the study is an OSA risk among people with CVD and the independent variables are demographics, race and socioeconomic factors (education, marital status, income, and employment).

3.5. Data analysis.

We will use measures of central tendencies and dispersion for continuous data and frequency distributions for categorical data. Chi square tests will be used to compare categorical data, and ANOVA will be used for continuous data.

3.5. a. Data storage and cleaning, Quality Assurance

The collected data will be entered into SPSS Version 22 (IBM Corporation, 2013) and will be stored in a separate computer designed for use by the OSA study coordinator and data manager. The data manager will be responsible for data entry, coding, verification, resolving or minimizing problems of missing data and clean the data for analysis.

All the participants will be given a study Id or an alphanumeric identifier to ensure the safety of the participant and the validity and integrity of the data. Such identifiers linking personal data to subjects will be maintained in a separate and secure file. The principal investigator, study coordinator and data manager will have access to the file containing personal information of the participants such as name, age, sex, address and contact information. The data will be coded and then entered into SPSS. Statistical analysis will be done using SPSS and data manager will assist the principal investigator in analyzing the data.

3.5. b. Data analysis to Achieve Aim 1

Hypothesis 1: Among CVD patients, CVD severity increases the risk of OSA.

The quantitative distribution of the variables will be expressed as descriptive statistics (frequencies, means and standard deviations, and range). The independent t - test will be used to analyze the relationship between CVD and OSA in the sample and to understand the degree to which presence of CVD is related to being at-risk for OSA.

3.5. c. Data analysis to Achieve Aim 2

Hypothesis 2: Among CVD patients, racial/ethnic minorities are at increased risk of OSA than white non-Hispanic patients.

To understand the correlation of race and risk of OSA, differences between groups in terms of level of OSA risk, age, neck size, etc., will be analyzed using Chi-square and ANOVA. The correlation will be studied among 4 groups: Patients with CVD who are White, non-Hispanic; Patients with CVD who are Black, non-Hispanic; Patients with CVD who are Asian and Patients with CVD who are Hispanic. These groups will be studied against three groups: “Low OSA risk”, “High OSA risk” and “Very-High OSA risk” among the sample. Apart from race, other sociodemographic factors such as income, education level and age will be correlated for each category of racial/ethnic group and the level of OSA risk in each category.

BUDGET

The expected budget for the study is $45,120 for the 2-year term. The majority of the budget expenses will be allocated towards collecting data for the study and paying the staff to carry out project related activities. This includes salaries for the Principal Investigator (PI), project coordinator, data manager, participant recruiter/ data collection team, and incentives of $20 for each enrolled participant. The Principal Investigator (PI) will insure that the research goals are met within the compliance regulations and will be responsible for successful implementation of the program. The PI will hire the project staff, prepare the required applications, supervise the team, write reports and disseminate the information and the total expected time devoted to those activities will be 52 weeks (13 months). The PI will be paid $15 per hour for at least 10 hours a week.

The project coordinator will be responsible for providing administration and coordination support for the study and will also insure proper communication with the partner recruitment sites. The expected time devoted to the project to carry out assigned activities for the project will be about 36 weeks (9 months) and the project coordinator will be paid $15 per hour for at least 10 hours a week. The data manager will be responsible for data entry, data coding and data analysis for the project. The expected time devoted to the project will be 48 weeks (12 months) and the data manager will be paid $15 per hour for at least 10 hours a week. Each data collection site will be allotted 2 study recruiters making a total of 8 study recruiters for the project. We plan to pay $10 per hour for 10 hours a week to each recruiter for an estimated 9 months of data collection. Therefore, the total direct expenses for the project are estimated to be $28,800.

The total indirect costs are estimated to be $16,320. The indirect costs include the travel costs, office supplies, computer and software for data management and analysis. The cost of statistical package software to carry out data analysis is $6000. The total cost associated with materials and supplies includes printing of questionnaires, stationary, printer ink, data backup and other office supplies. Projected travel expenses include trips to the recruitment sites by the recruitment staff and trips by the PI and project coordinator for meetings with the recruitment sites. In addition, we also request 10% overhead expenses to cover additional costs.

BUDGET ITEM	**AMOUNT**	**SUB-TOTAL**
1. **Direct Costs**		
a. Personnel		
Principal Investigator	$ 7800	
Project Coordinator	$ 5400	
Data Manager	$ 7200	
Study Recruiters (8)	$ 3600	
b. Incentives for participants (240 participants)	$ 4800	
Total Direct Expenses		**$28,800**
3. **Indirect Costs**		
Office Supplies	$ 3000	
Travel expenses	$ 3000	
Statistics Software	$ 6000	
Overhead expenses	$ 4320	
Total Indirect Expenses		**$ 16,320**
TOTAL EXPENSES		**$45,120**

TIMELINE

The project timeline is presented in the Table 1 below. The study is compatible with a 2-year time frame. During the first 5 months, project staff (study recruiters, data manager, and project coordinator) will be hired and IRB consent will be approved. An estimated 2 months for selecting the data collection sites, i.e. the primary care centers from selected neighborhoods and 2 months for training of the team members will be needed. The expected time for data collection is about 9 months and 6 months of data analysis, report writing, and dissemination of information and study findings to the community member, Community-Based Organizations, primary care centers and health agencies.

Recommendation #1: Educate about dual use when prescribing contraceptives 25
Recommendation #2: Raise Awareness of STD risks 26
Recommendation #3: Develop condom negotiation skills 27

CONCLUSION 28

Abstract

Background: Sexually transmitted diseases (STDs) and unplanned pregnancy continue to disproportionately affect female adolescents and young adults in the U.S. **Problem:** There are numerous available safe sex methods available for adolescent and young adult females, though there is no singular method that provides adequate protection against both STDs and pregnancy. With no one method providing complete protection, the practice of dual use methods (i.e., both condoms and hormonal/IUD protection) should be encouraged. **Methodology:** A systematic literature review was conducted using peer-reviewed articles gathered from online databases published between 1997-2014. The search was performed using key words such as "condoms," "adolescent condom use," "predictors of condom use," "risky sexual behavior and adolescents," " parental views on condom use," " rates of STDs," "oral contraceptives and adolescents," "dual use and adolescents," and "sexual education". Eighteen articles were reviewed. **Findings:** Race/ethnicity, age, level of education, age of sexual debut, type of health insurance, and perceived risk are all important factors in determining a female's choice behind safer sex practices. Rates of dual use, the most complete method of safe sex, remain low across all groups within the studied population. **Implications**: Adolescents and young adults need to be educated in the importance of using both condoms and hormonal/IUD protection to mitigate the risks of STDs and pregnancy. This population should be educated in the importance of continuing condom use even after the initiation of hormonal/IUD methods.

Introduction

Sexually transmitted diseases (STDs) and unplanned teen pregnancy remain a problem that disproportionally affects the adolescent and young adult population of the United States (East, Jackson, O'Brien, & Peters, 2007). Adolescence is defined as the years between 15 and 19 years old. According to World Health Organization (WHO), young adult refers to those aged 15-24, an overlap between adolescence and post adolescence (East, Jackson, O'Brien, & Peters, 2007). Sexually transmitted diseases are infections that can be acquired through sexual activity with an infected partner (Centers for Disease Control [CDC], 2011a; National Institute for Health [NIH], 2014). There are over twenty types of STDs (NIH, 2014). Herpes simplex virus type 2 (HSV-2), or genital herpes, hepatitis B (HBV), and human immunodeficiency virus (HIV) are all lifelong infections that make up about a quarter of STDs, but others can be treated and cured if detected and diagnosed (CDCa, 2013). Teen pregnancy has also been associated with a lifelong negative impact. An increase of safer sex practices among female adolescents and young adults may help to mitigate the risks of STDs and unplanned pregnancy among the female adolescent and young adult population of the United States.

Background and statistical overview

STDs represent a serious public health problem, with an estimated prevalence of 110 million cases in the United States and an estimated 20 million new cases each year (CDC, 2014). In addition to the health consequences of STDs, there are also serious financial implications. The CDC (2014) estimates that STDs cost the United States about $16 million per year in healthcare costs. Moreover, the actual prevalence rates of some STD cases likely surpass the numbers reported by the CDC due to undiagnosed cases and infections such as human papillomavirus (HPV) and genital herpes that are not reported to the CDC (CDC, 2013a). In the

United States, almost half of the new cases of STDs occur among adolescents and young adults aged 15-24 years old (CDC, 2013a). Every year approximately one in four sexually active 15-24 year olds will contract some type of STD (Kaiser Family Foundation [KFF], 2013a). Young adults and adolescents aged 15-24 years old account for 26% of newly reported cases of HIV, which is mostly acquired through sexual contact (KFF, 2013b).

Female adolescents and young adults are an important population to consider because women may be less likely than men to have symptoms of STDs, or their symptoms may be less noticeable, making it more difficult to diagnose. For example, men may develop sores on their penises from STDs that are more visible than a genital ulcer would be inside the vagina (CDC, 2011a). When compared to older women, young women are more vulnerable to sexually transmitted diseases because of higher rates of cervical ectopy in young women, a common biological process that can occur during adolescence and, "is thought to increase risk … by exposing columnar epithelium to a potential infectious inoculum" (Chambers & Rew, 2003; Lee, Foley, & Tobin, 2006, pp.104). Moreover, many adolescent females have little knowledge of the symptoms of STDs allowing the disease to go undetected and thus undiagnosed (East et al., 2007). Health complications can affect men and women, but young women face the most serious long-term effects, including infertility (CDC, 2014). Other risks associated with untreated STDs include pain, cervical cancer, and pelvic inflammatory disease (Paterno & Jordan, 2012).

Aside from their high risk for STDs, female adolescents in the United States are also at a high risk for unintended pregnancy. In 2009, the birth rate among U.S. teens decreased to 39.1 births per 1,000 females, a 37% decrease from the birth rate of 61.8 per 1,000 females in 1991. Despite this decline, the United States still has some of the highest rates of adolescent pregnancy

in the developed world (Chambers & Rew, 2003). In fact, the teen birth rate in the United States is as much as nine times higher than other developed countries (CDC, 2011b). Teen pregnancies account for roughly 10% of births in the United States, as well as one in four of non-marital births (Basch, 2011; Patel & Sen, 2012).

Teen pregnancies in the United States are associated with high economic and social costs. The total U.S. government expenditure of teen pregnancy was $11.3 billion in 2006 (Patel & Sen, 2012). Babies born to adolescents are more likely to have lower birth weight and higher rates of death in infancy than seen in pregnancy from adults (CDC, 2011c). Teen mothers themselves also experience adverse effects. Studies indicate strong associations between teen pregnancy and low employment, low levels of education, and low socioeconomic status (Patel & Sen, 2012). Teens that become pregnant are also less likely to finish high school and college. Unfortunately, children born to teenage mothers are also more likely to become teen moms themselves (Basch, 2011).

Racial and ethnic differences in sexual behavior. According to the 2011 Youth Risk Behavior Survey (YRBS), about half of (46%) of American female high school students have engaged in sexual intercourse (CDC, 2011c). Among females, black students are more likely to engage in sexual intercourse (58%) than white (45%) and Hispanic (45%) adolescents. For male students, black adolescents (72%) reported the highest rates of sexual intercourse when compared to Hispanic (53%) and white (40%) students (CDC, 2011c). Among white teens, the birth rate was reported as 25.6 per 1,000 females (CDC, 2011c). In 2009, the birth rate among black teens was 59 per 1,000 females and 70.1 per 1,000 females among Hispanic adolescents (CDC, 2011c). While there has been an overall decrease in sexual intercourse among male and

female students, there has been no decline of sexual intercourse among white female students, Hispanic female students, or Hispanic male students (CDC, 2011c).

Little research exists on the sexual practices of Asian/Pacific Island adolescents, but adolescents of other races and ethnicities tend to have higher rates of STDs and pregnancy than Asian and Pacific Island adolescents. It is important for researchers to further assess the sexual behavior of Asian and Pacific Island adolescents, as Asian and Pacific Islanders are one of the fastest growing populations in the United States (Schuster, Bell, Nakajima, & Kanouse, 1998). The research that does exist indicates that white adolescents are 2.3 times more likely to communicate about STDs than Asian adolescents. This finding may signal that Asian adolescents may be a more vulnerable and harder to reach population than white adolescents (Hou & Basen-Engquist, 1997).

Use of protection. According to the 2011 YRBS, 15.1% of American female high school students did not use any sort of protection in their last sexual encounter (CDC, 2011c). Research shows a decrease in condom use as students progress through high school. Basch's study reveals condom use decreased from 69.3% amongst 9th grades to 54.2% amongst 12th graders (Basch, 2011). These statistics indicate the continued public health problem affecting this population and further emphasizes the importance of understanding the predictors of safer sex practices.

Much of the previous research has been focused on condom use as an indicator of safer sex practices, but Healthy People 2020 encourages dual use protection among adolescents since condoms provide only modest protection against pregnancy. Condoms have a 2% pregnancy rate when used ideally and up to a 17.4% pregnancy rate when used typically (Brown, Hennessy, Sales, DiClemente, & Salazar, 2011; CDC, 2013b; Ott, Adler, Millstein, Tschann, & Ell, 2002; O'Leary, 2011). Dual use is defined as combining the use of a condom with a form of hormonal

contraception such as oral contraceptives (Morroni, Heartwell, Edwards, Zieman, & Westhoff, 2014). Since female adolescents in the United States report low rates of dual use, it is important to understand the factors behind the choice for each method of protection including no protection, condom use only, non-barrier protection only, and dual use methods to properly address the issues that may affect dual use.

Dual use barriers

Adolescents in general associate condom use with pregnancy prevention only. Holding true to that belief, once female adolescents switch to contraceptives, condom use tends to decrease. Only one in six female adolescents use condoms partnered with another form of contraception (Chambers and Rew, 2003). A problem among the general adolescent population is the ambiguity of the terminology "safer sex" and "contraception". Safer sex applies to preventing the transmission of diseases as well as preventing unplanned pregnancy. Contraception only applies to avoiding pregnancy (East et al., 2007). The ambiguity leads to the misconception that even non-barrier contraceptives are a safer sex practice protecting against both STDs and pregnancy. In fact, one in five adolescents believe that an oral contraceptive pill is effective against the risk of STDs (KFF, 2013b). Unfortunately there is no one form of protection that defends against both STDs and pregnancy. Male condoms only provide modest protection against pregnancy when compared to other forms of protection (Tyler et al., 2014). Conversely, non-barrier forms of protection such as oral contraceptives provide high protection against pregnancy, but do not protect against STDs (East et al., 2007; Tyler et al., 2014).

Since each form of protection carries its own benefits and risks, Healthy People 2020 encourages dual use protection among female adolescents and young adults to create a more complete safer sex practice (HHS, Healthy People 2020, 2013). In order to achieve the highest

rates of protection against both STDs and pregnancy, it would be prudent to encourage the dual use of condoms and non-barrier pregnancy protection.

Table 1. Classification of types of safe sex practices

Category	Description
Condoms only	• Male or female condom
Non-barrier only	• Hormonal methods (oral contraceptives, patches, injections, vaginal rings, emergency contraceptive pills) • Implantable rods • Intrauterine devices
Dual Use	• Male or female condom plus a non-barrier form of contraception (see above)
No protection	• Includes withdrawal and fertility awareness based methods (ovulation tracking)

Methodology

A literature search was conducted using peer-reviewed articles gathered from online databases and statistical reports collected from government and foundation websites for my research. I performed my search using key words such as "condoms," "adolescent condom use," "predictors of condom use," "risky sexual behavior and adolescents," "parental views on condom use," " rates of STDs," "oral contraceptives and adolescents," "dual use and adolescents," and "sexual education." The search was limited to English language only publications published primarily between 1997 and 2014. The search was not limited to studies in the United States. Studies that focused primarily on males and adults over the age of 24 years were excluded. Overall 18 studies were reviewed.

Findings

This paper explores the differences amongst female adolescents and young adults, 15 to 24 years of age, and their choices behind various forms of safer sex practices. In a review of 18 research articles, I examine the attributes of female adolescents and young adults who use methods of protection within the following four categories: no protection, condoms only (e.g. male and female condoms), non-barrier protection only (e.g. oral contraceptives, intrauterine devices, and shots), and dual use, i.e., condom and non-barrier protection together. Social and demographic factors emerged as consistent themes in understanding the use of safer sex practices among female adolescents and young adults. These factors are further explained in Table 2.

Condom use only

Eleven studies focused on condom use among female adolescents and young adults. Most research showed condom-only practices were the most common form of protection among female adolescents and young adolescents.

Demographic factors. Certain demographic factors can have an effect on the likelihood of condom use among female adolescents and young adults. These factors include race/ethnicity, age, and education (Manlove, Ikramullah, & Terry-Humen, 2008; Paterno & Jordan, 2012). For example, according to the 2011 YRBS, 34.7% of African American adolescents reported not using a condom in their last sexual encounter, where as 41.6% of Hispanic adolescents reported not using a condom. The YRBS also stated that 40.5% of white adolescents and 33.8% of American Indian/Alaskan adolescents reported not using a condom. The percentage of Asian adolescents not using a condom was reported as N/A, since the YRBS only reported percentages for races and ethnicities for which statistical significance was found (CDC, 2011c). While none of the previously stated percentages are desirable, it is clear that

there are discrepancies in condom use among various populations. According to Manlove, Ikramullah, and Terry-Humen (2008) African Americans adolescents report higher condom use than other races and ethnicities. This finding is further exemplified by the YRBS findings stated above. According to YRBS, African Americans had the lowest rates of no condom use (34.7%) compared to other races and ethnicities (CDC, 2011c). First generation Hispanic adolescents are only half as likely as white adolescents to report consistent condom use (Manlove et al., 2008). Adolescents and young adults who are either African American or Hispanic were more likely to use condoms alone over dual use if compared to white adolescents (Tyler et al., 2014; Cavazos-Rehg, 2010).

Age and education. Females with less than a 12th grade education were also more likely to report condom-only use over dual use. Younger adolescents may be more likely to use condoms only than any other method of protection. Some studies indicated that those aged between 15-19 were more likely to use condoms only when compared to older adolescents. Other studies showed that those less than 17 years old were more likely to use condoms only (Tyler et al., 2014; Ott et al., 2002). Generally, those towards the younger end of the 15-24 year old age range are more likely to use condoms only.

Social factors. An important factor of condom use among adolescents and young adults was the perceived risk of STDs. Those who reported a high self-perceived risk of STDs continued to report consistent rates of condom use (Ott, Adler, Millstein, Tschann, & Ellen, 2002). When a female felt there was a high risk of STD, she was more likely to use a condom during sex. Health insurance was also a significant variable among females who use condoms only. Those with no health insurance were more likely to use condoms only when compared to those with health insurance. This may be due to a lack of access to prescriptions for other

methods (Tyler et al., 2014). Adolescents who are looking for low cost measures of protection also report condom-only use (Cavazos-Rehg, 2010). Another interesting factor associated with condom-only use was found among females without previous pregnancies. Females who were never pregnant were more likely to use the condom-only method over the dual use method (Tyler et al., 2014).

Relationship type. Partner type is also a significant factor in condom use among female adolescents. Research indicates that female adolescents and young adults are more likely to use condom-only protection with casual partners (Tyler et al., 2014). Females entering into new relationships were likely to use only condoms during sexual intercourse. Females who did not yet trust their new partners used condoms more than those in steady relationships. Overall, trust is an important issue in female adolescents deciding to use a condom. Those who reported high levels of trust felt that they no longer needed to use a condom (Roye, 2001).

Age of sexual debut. Age of sexual debut played a role in females using only condoms for safer sex protection. Those who initiated sexual intercourse at a later age seemed the most likely to use the condom-only method of protection. Tyler et al. (2014) found that those who were 18 or over at sexual debut tended to use condoms alone as their regular form of protection. Additionally, adolescents who used a condom at their sexual debut were more likely to consistently use condoms during later encounters than those who did not use a condom at sexual debut (Shafli, Stovel, & Holmes, 2007).

No protection

No protection is unprotected sex, but can include the use of methods that do not provide effective protection against STDs and pregnancy. Withdrawal, also known as the pull out method is included in the no protection category. Five studies focused specifically on no

protection as a category for safer sex. Despite the high levels of risk faced by adolescents, many still forgo protective measures. According to the CDC YRBS, while 35.2% of female adolescents were sexually active, 15.7% did not use any form of protection (CDC, 2013c).

Demographic factors. Higher rates of unprotected sex were seen in Hispanic adolescents and young adult females when compared to females of the same age of other races and ethnicities (American Academy of Pediatrics, 2013; Cavazos-Rehg, 2010). According to 2013 YRBS, 23.7% of Hispanics, 21.2% of blacks, 11.9% of whites, and 13.7% of those with multiple races participated in unprotected sex. The survey did not provide statistics for Asians, Native Americans, or Native Hawaiian/other Pacific Islanders because the subgroup sizes were too small to produce significant findings (CDC, 2013c). Lower socioeconomic status may be associated with higher rates of risky sexual behavior among adolescents, which includes not using protection during sex (Manlove et al., 2008). Rates of unprotected sex were lowest among those with some college education (Tyler et al., 2014).

Social factors. Female adolescents and young adults were most likely to use no form of protection with main partners (27.4%) when compared to casual partners (18.9%). Main partners were defined as someone the female was serious about (Ott et al., 2002). Females were also less likely to use protection if she felt that there was a low risk of getting pregnant and acquiring STDs (Ott et al., 2002). Sexual debut was an important factor in predicting safe sex protection among female adolescents and young adults. Rates of practicing safe sex increased as the age of sexual debut increased (Cavazos-Rehg et al., 2010). Research by Manlove and associates found that the lack of any type of sexual education may lead to lower rates of safe sex practices among adolescents. Statistically, adolescents who did not receive formal sex education were two times less likely to use protection at sexual debut (Manlove et al., 2008; American Academy of

Pediatrics, 2013). Poor timing of parental sex discussions has been associated with lower rates of safer sex protection. Maternal discussions about safe sex prior to an adolescent's first sexual encounter may lead to a higher likelihood of prolonged safe sex practices, but sex discussions that occur after sexual debut did not prove to be significant (Millier, Levin, Whitaker, & Xu, 1998). The research on education was limited to the umbrella of safer sex practices and did not provide information specific to the type of method used.

Non-barrier methods only

The non-barrier only category refers to the use of a type of intrauterine device or hormonal method without the added protection of a condom. This category encompasses the use of hormonal methods such as oral contraceptives, contraceptive patches, injectable birth control, vaginal rings, and copper and hormonal intrauterine devices. Six studies focused on the non-barrier method of protection. Hormonal contraceptives and intrauterine devices provide high levels of protection against pregnancy, reporting annual failure rates of 9% and between .2%-.8% respectively (CDC, 2014). Both percentages reflect typical use of these methods rather than perfect use. Most of the studies reviewed focused on hormonal methods of contraception, specifically oral birth control pills over intrauterine devices. This may be due to the low rates of IUD use among adolescents. According to YRBS, only 1.6% of those surveyed used an IUD (CDC, 2104). Intrauterine devices and hormonal methods of contraception are reported to be the most successful approaches to prevent pregnancy, but neither strategy offers protection against STDs (Morroni et al., 2014; Tyler et al., 2014).

Demographic factors. Oral contraception has been reported among the most commonly used methods of hormonal contraceptives (Morroni et al., 2014). Some studies even found that "the pill" was more common than condom use among adolescents and young adults. "The pill"

typically refers to the oral contraceptive hormonal method. Bearinger and Resnick (2003) found that 43.8% of those interviewed used an oral contraceptive, compared to 36.7% who used a condom (2003). The tendency to use only a non-barrier method over other methods may be associated with demographic factors including race, age, and level of education. Non-barrier use was found to be highest among non-Hispanic whites and least common among Hispanics (CDC, 2014; Tyler et al., 2014). According to YRBS, the use of hormonal methods alone was found to be lowest among 9th grade females (14.7%) when compared with 10th grade (19.2%), 11th grade (23.2%), and 12th grade (27.6%) females (CDC, 2014). Females over 17 and those that reported high school as the highest level of education were most likely to report using a non-barrier method as the only form of protection (Tyler et al., 2014).

Relationship status. Three studies also found that relationship status was strongly associated with a female deciding to use only a non-barrier method of protection. The majority of adolescents using only a non-barrier contraceptive were in long term relationships. These adolescents also reported sexual activity with only one male partner (Roye, 1997; Tyler et al., 2014). One study found that female adolescents were more likely to use only a non-barrier method with a main partner (23%) when compared to the 5.4% who only use the same method with a casual partner (Ott et al., 2002). Roye and Seals (2001) found that female adolescents reported using only a non-barrier method if there was a significant amount of trust in the relationships. Age of sexual debut was also associated with using only a non-barrier method of protection. The research found females younger than 16 at age of sexual debut to be most likely to use only a non-barrier method of protection (Tyler et al., 2014).

Perceived risk. Perceived risk and views on pregnancy were also indicators of using only a non-barrier method. Those who had a high-perceived risk of pregnancy but a low-

perceived risk of STDs were likely to use only a non-barrier method (Ott et al., 2002). The females using only a non-barrier method were also less likely to have been recently tested for an STD (Tyler et al., 2014). Adolescents and young adults who reported using only a non-barrier method of protection tended to view pregnancy with their main partner as highly negative (Ott et al., 2002).

Dual use methods

Dual use refers to the combination of a non-barrier method coupled with either a male or female condom. As previously stated, aside from abstinence, there is no single safer sex practice that promises complete protection against both STDs and pregnancy (Bearinger & Resnick, 2003). To provide full protection, it is now recommended for adolescent and young adult females to practice dual use. Condoms can provide protection against STDs and pregnancy, but the failure rate of condoms among this population can be as high as 18% (CDC, 2014). Since correct and consistent condom use was found to be low among adolescents and young adults, dual use is the preferred method of protection (Tyler et al., 2014). Eleven studies focused on the dual use method of protection. Many of the studies reviewed were cross sectional. While statistics of dual use among adolescents and young adults ranged from as low as 3%-5% among some populations to as high as 14%-20% among other populations, overall dual use among female adolescents and young adults in the United States remains quite low (Morroni et al., 2014). In fact, according to YRBS, national dual use is reported at only 8.8% (CDC, 2014).

Many studies have expressed an inverse relationship between condom use and initiation of hormonal methods. As oral contraceptives, or other hormonal methods are initiated, condom use was found to decrease (Ott et al., 2002; Morroni et al., 2014; Tyler et al., 2014). Studies have indicated that adolescent and young adult females who use non-barrier protection were less

likely to use condoms than other sexually active females (Roye, 1997). Upon initiation of hormonal methods/IUDs, adolescent and young adult females decrease condom use stating that there is adequate pregnancy protection from the hormonal or intrauterine device (Roye, 1997). One study even found that 48% of participants discontinued condom use within six months of beginning oral contraceptives (Morroni et al., 2014). While interviewing adolescent girls about condom use, one young female stated that she did not use a condom because she was on the pill and could not get pregnant (Roye & Seals, 2001).

Demographic factors. According to the results of the last YRBS, dual use rates differ by race/ethnicity. White females were more likely to report dual use than black and Hispanic females. Hispanic females were the least likely to practices dual use, with only 3% of those surveyed reporting this practice (CDC, 2014). As stated previously, there was not enough data on other ethnicities for the YRBS report to derive reliable statistics. As with non-barrier methods, age and education were associated with rates of dual use. Dual use was highest among adolescent and young adult females with some college, as well as among females over the age of 17 or 18 (Ott et al., 2002; Tyler et al., 2014). The studies could not definitively determine if age and education were singularly associated with dual use since age and level of education may be a proxy for one another.

Social factors. A female's age of sexual debut was also associated with the tendency to practice dual use. Females 18 and older at sexual debut were more likely to utilize dual methods than those who were younger than 18 at sexual debut (Tyler et al., 2014). Health insurance was also associated with rates of dual use among this population. Tyler and associates (2014) found that dual use rates were highest among females with access to private health insurance and lowest among those with no health insurance. Those with public health, i.e. Medicaid, reported

higher rates of dual use than those with no health insurance (Tyler et al., 2014). Adolescents and young adults who reported receiving welfare within the last 12 months were less likely to practice dual use methods when compared with those not receiving welfare (Tyler et al., 2014).

Perceived risk. Adolescents and young adults tend to view any measure of protection as a way to prevent pregnancy only. An important barrier to dual use is the desire to avoid pregnancy over disease among this population (O'Leary, 2011). Adolescents may be more familiar with the concept of pregnancy and can more easily visualize the associated risks (Roye, 1997). One study found that there were similarities between those who used a condom for protection against both STDs and pregnancy and the likelihood of dual use rates (Tyler et al., 2014). When a female had a high-perceived risk of STDs and previously used condoms to prevent against them, she was less likely to forgo condom use once a non-barrier method, such as oral contraception, was initiated (Ott et al., 2002; Tyler et al., 2014). Females who practiced dual use were concerned with protecting against both disease and pregnancy. Females who had been previously diagnosed with an STD were also likely to practice dual use (Tyler et al., 2014).

Relationship type. Relationship status was associated with dual use rates among this population. Females in monogamous relationships reported decreased rates of condom use among those who were using a non-barrier method of protection. Using non-barrier methods did not affect condom use among adolescents and young adults in casual relationships. This finding reflects higher rates of dual use among casual relationships than main partner relationships. (Ott et al., 2002; O'Leary, 2011; Tyler et al., 2014). In one study, only 13.9% of females reported dual use with a main partner, compared to 23.4% of females who reported dual use with a casual partner (Ott et al., 2002). Females who reported not trusting their partners were more likely to

report higher rates of dual use since these females were less likely to forgo condom use once initiating non-barrier protection (Roye & Seals, 2001).

Table 2. Findings based on review of 18 articles

	Demographic Factors			Social Factors				
Method of protection	**Race/ Ethnicity**	**Education**	**Age**	**Perceived risk of pregnancy**	**Perceived risk of STD**	**Partner type**	**Age of sexual debut**	**Health insurance**
No protection	African Americans and Hispanics most likely	≤ 12th grade	9th grade	Low	Low	Main	< 15 years old	Public
Condoms only	African Americans most likely	≤ 12th grade	< 17 years old	Not significant	High	Casual	≥ 18 years old	None
Non-barrier only	White non-Hispanics and Hispanics most likely	HS graduate or equiv.	> 17 years old	High	Low	Main	≤ 15 years old	Private
Dual method	White non-Hispanic most likely	College degree or some college	≥ 18 years old	High	High	Casual	≥ 18 years old	Private

Note. Three of the studies reviewed discussed sexual education and its relation to safer sex practices among adolescent and young adult females. The research found that those who receive sexual education are more likely to practice safe sex. The research did not specify which forms of protection increased as a result of receiving sexual education.

Discussion

This paper reviewed the factors behind the safer sex choices among adolescent and young adult females in the U.S. The studies reviewed support the importance of increasing the occurrence of dual use for safer sex among U.S. adolescent and young adult females. All of the studies reported low rates of dual use practices when compared with other methods including, no protection, condom use only, and non-barrier methods. Age, education, race/ethnicity, perceived risk, partner type, age of sexual debut, and type of health insurance were all factors which affected safer sex choices among this population. Continuing to understand these factors will help to promote and increase the rates of dual use among adolescent and young adult females.

Strengths and weaknesses of literature

A major strength of the existing literature was that the studies focused on adolescents and young adults who did not intend to get pregnant in the near future. Removing these females from the data pool helped to ensure that those forgoing specific methods were not doing so in order to achieve a certain result. Another strength was the type of study design used in two of the studies. Bearinger and Resnick (2003) used a longitudinal study and Morroni and associates (2014) used a cohort study. This allowed both studies to include the effects of time as a factor of choices.

Conversely, the existing research also has many limits. Firstly, there are still many studies conducted that do not compare rates of dual use with other methods. The YRBS only began collecting data on dual use in 2011. With no previous data, the most recent YRBS was unable to provide trends and analysis for dual use rates. Another limitation is that most of the studies are cross-sectional. There were very few prospective studies. Cross-sectional studies force researchers to draw upon inferences to determine what occurs after the initiation of non-barrier methods. Studies also often questioned participants about the method used “at last sex.”

Using this method may not portray an accurate picture of a female's typical safe sex method of choice. The study performed by Ott and associates may have been biased since participants were recruited from HMO clinics. This study may have investigated a specific population that was not representative of the whole population. Lastly, the studies all used self-reported data. Adolescents and young adults may not be truthful when reporting preferred and typical safer sex methods. Participants may exhibit social desirability bias and try to provide the responses they deem to be socially acceptable.

Issues examined in literature

Sexual Education. As stated in the findings, females who did not receive sex education were twice as likely to forgo protection during their first sexual encounter (American Academy of Pediatrics, 2013). Despite the benefits associated with sex education, many states still choose to encourage abstinence focused sexual education programs. A national level data analysis found that abstinence-only education does not reduce teen pregnancy. In fact, the same study found that abstinence-only education might actually increase rates of teen pregnancy (Stranger-Hall & Hall, 2011). The United State has two types of federal funding for sexual education: abstinence-only education funding and funding for research and evidence based prevention programs. States can now determine the best education option to prevent teen pregnancy. Of the 48 states analyzed, 21 states opted for abstinence-based education in their state laws and policies on sexual education. Eleven states covered abstinence simply as a measure of safe sex and nine states did not mention abstinence at all. The level of abstinence education was positively associated with teen pregnancy rates. The states that promoted abstinence-only had higher rates of teen pregnancy. States with less emphasis on abstinence saw lower teen pregnancy rates (Stranger-Hall& Hall, 2011).

As demonstrated above, research implies the importance of adolescents receiving comprehensive sex education. Comprehensive sex education discusses abstinence, but also educates students about condoms and contraceptives (Kirby, 2007). Regardless of which form of sexual education is taught, it seems that the information does not necessarily have to be factual. According to the National Conference of State Legislatures, only 19 states require that when provided, sex education must be medically factual or technically accurate. Additionally, 35 states and the District of Columbia give parents the choice to opt-out of sexual education for their children (National Conference of State Legislatures [NCSL], 2014). This implies that even if adolescents could potentially receive sexual education, they can be either getting the wrong information or be denied the education as requested by their parents. Most of the research reviewed only discusses the effects of sexual education on teen pregnancy but not on STDs. It would be prudent for research to observe the effects of education about STDs in order to understand how to best promote dual use practices among adolescents and young adults. As stated above, adolescents and young adults themselves are also more concerned with pregnancy than disease. The lack of research on the effects of sex education on the rates of STDs displays an important limitation. Adolescents and young adults need to be educated about the continued risks of STDs.

Health insurance. Research found that health insurance was associated with the choice of safer sex practices among adolescent and young adult females. One study found that those with private health insurance were more likely to practice dual use than those with government health insurance or no health insurance (Tyler et al., 2014). Those without health insurance may have less access to prescription contraceptives. Without access to prescriptions, these females may not have been able to attain oral contraceptives, one of the most popular non-barrier

methods of protection (Morroni et al., 2014). It will be interesting to see if these statistics change in future studies after the full implementation of the Patient Protection and Affordable Care Act. Since the PPACA mandates health coverage for most Americans, more people should have access to prescription use. Furthermore, some insurance plans will not charge a co-pay for certain brands of contraceptive options under the PPACA (KFF, 2014). By removing the financial cost, females may be more likely to opt for use of non-barrier methods as an added component of safer sex practices.

High-risk groups. Some studies reviewed high-risk groups of adolescents and young adults. High-risk groups are made up of adolescent and young adult females at greater risk for unintended pregnancy and STDs because of their risky sexual behavior such as a high number of sexual partners and early sexual debut (Tyler et al., 2014). Unfortunately, high-risk groups are even less likely to practice dual use methods of protection. One study found that females who reported six or more partners were less likely to report dual use (O'Leary, 2011). This finding may conflict with other studies that found higher rates of dual use among those with multiple casual partners, but it is important to understand that there may be females within the high-risk pool who are not practicing the best methods of safer sex practices. Those who are at a higher risk of pregnancy and disease because of riskier behaviors may be continually putting themselves in high-risk situations.

Perceived risk. Perceived risk was a common factor of dual use across many of the studies. Most females in this population were less concerned with the risk of disease than the risk of pregnancy (Roye, 1997). Viewing contraceptives only as a way to decrease the risk of pregnancy may be related to adolescents and young adults forgoing condom use after the initiation of oral contraceptives or other non-barrier methods. As discussed above, condom use

tends to decrease after a female begins to use a hormonal/IUD method of contraception, which may create a new risk pool of adolescents. One study reported relatively new concerns about a possible risk of an increase of HIV among oral contraceptive users since users are unlikely to continue condom use (Morroni et al., 2014). Two studies interviewed adolescents and young adults about past condom use, and both studies reported females stating that condoms were not used at last sex because there was no longer a risk of pregnancy after beginning oral contraceptives (Ott et al., 2002; Roye & Seals, 2001).

Parental discussion. Discussing sex is considered a private matter in the United States, and adolescents report that sex is the topic most avoided with their parents. Mothers who are not confident in their knowledge of sexuality and STDs tend to communicate less effectively about condom use (American Academy of Pediatrics, 2013). Some parents feel that they do not have the skill set to discuss such issues with their children and tend to shy away from this type of conversation (Afifi, Joseph, & Aldeis, 2008). When parents communicate openly with their children about sexual issues, these children are more likely to delay sexual initiation, have fewer partners, and practice safer sex (O'Sullivan, Meyer-Bahlburg, & Watkins, 2001). Interestingly, many parents discuss the risks of sexual behavior such as HIV, STDs, and pregnancy, yet only one quarter of parents advise their children on where contraceptives can be obtained to prevent against said risks (Afifi, Joseph, & Aldeis, 2008). Research in this area is often inconsistent due to a lack of standard to measure communication between children and their parents (O'Sullivan et al., 2007).

Summary and Recommendations

The findings from the 18 articles reviewed support the need for action in order to increase the rates of dual use among adolescents and young adults. Since Healthy People 2020 added

increasing dual use rates as a goal for adolescents, this is an excellent opportunity to identify action points to achieve this goal. There are teaching opportunities that need to be addressed in order to achieve higher rates of the safer sex recommendations as set by the CDC and Healthy People 2020 (CDC, 2104; HHS, 2013). Longitudinal studies and cohort studies may best reflect the effectiveness of implemented interventions.

Recommendation #1: Educate about dual use when prescribing contraceptives

The reviewed studies showed a decrease in condom use after the initiation of hormonal contraceptives. Prescribing these contraceptives may provide a unique teaching opportunity. Physicians should take the opportunity to promote the importance of continued condom use even after beginning a non-barrier form of contraceptive. Young adults and adolescents should be reminded at this juncture that non-barrier methods do not provide protection against disease. This recommendation is directed at the professionals prescribing non-barrier methods of protection. One study analyzed a group of adolescent and young adult females at initiation of oral contraceptives and found that only 28% of participants were advised to always use a condom after beginning the use of oral contraceptives (Morroni et al., 2014). This is a strikingly low number. This is a missed opportunity for physicians to provide pertinent information to adolescent and young adult females. Physicians themselves also must be educated about hormonal contraceptives. One study found that some physicians did not prescribe hormonal contraceptives to younger adolescents because of misconceptions associated with future infertility (Swanson et al., 2103). It is important for physicians to take this learning opportunity to educate young women and raise their perceived risk of STDs.

As stated above, the implementation of the ACA may lead to higher rates of health insurance across the population. If more adolescents and young adults have access to care, there

may be an increase in the amount of females visiting physicians for hormonal contraceptives. As a result of the ACA, even more females could be educated about the importance of dual use methods at the initiation of hormonal contraceptives.

Recommendation #2: Raise Awareness of STD risks

Since findings from this review found that female adolescents and young adults are more concerned with preventing pregnancy than with protecting against STDs, it would be beneficial to raise the perceived risk of STDs among this group. Programs that focus on STDs and encourage condom use need to be implemented. These types of interventions tend to increase condom use even among female adolescents already using hormonal contraceptives (O'Leary, 2011). In addition to the lack of concern among adolescents, education programs also seem to be more focused on mitigating teen pregnancy than in reducing rates of STDs. If educators do not emphasize the risks of STDs, then young women will have a difficult time in realizing the importance of continuing to protect against STDs even after initiating a hormonal method. This recommendation is directed at the state level since states have the power to determine the type of sexual education that will be taught. With only 22 states and the District of Columbia requiring some form of sex education, many students are not receiving any sort of information about safe sex practices. Also, only 39% of high schools taught students how to correctly use a condom in their health education courses (NCSL, 2014). More states need to begin to require sex education in schools in order to emphasize the importance of protecting against not only pregnancy but also against STDs. The programs that already exist in schools should be re-focused to emphasize the risks of STDs in order to achieve higher rates of dual use.

According to the literature, those with a low-perceived risk of STDs were less likely to use condoms (Ott et al., 2002). One study performed an intervention based on an HIV

prevention program called Project RESPECT. This study provided black and Latina adolescent girls who were already on oral contraceptives with either a video, Project RESPECT counseling, both video and counseling, or usual care. Usual care consisted of no intervention. The study found that within the first three months, those receiving both interventions were more likely to have used a condom at last sex than those who received no intervention or only one form of intervention. This study found that as a result of a condom-focused intervention many of the participants became dual users (O'Leary, 2011). This study shows the importance of condom-focused interventions to increase the perceived risk of STDs.

Recommendation #3: Develop condom negotiation skills

As mentioned above, hormonal/IUD methods do not provide protection against STDs. Despite this drawback, female adolescents and young adults may be attracted to this method of protection because it does not require male participation. This is highly important because it is a method that allows the females to take greater control of their sexual experiences (Morroni et al., 2014). It is beneficial for females to be in control of these situations, but using non-barrier methods alone still leaves this population vulnerable to STDs. Female adolescents and young adults may benefit from increasing condom negotiation skills to ensure confidence in providing themselves with complete protection. This recommendation is directed at both education systems and parents as explained below.

Condom negotiation is a particularly important skill for females since males and females tend to have different beliefs regarding advantages of condoms (Calsyn et al., 2013). Female adolescents have reported lower condom use because they expect their partners to have negative attitudes towards condoms (Staras et al., 2013). Men are more likely to portray condoms negatively and often state that condoms reduce their sexual pleasure, do not fit properly, and

interrupt the mood (Calsyn et al., 2013; De Visser, 2004). Unfortunately, many males and females still consider that it is the male's role to decide whether to use a condom. This attitude affirms older cultural beliefs that females should be passive in sexual matters (French & Holland, 2013). Schools that teach sex education should incorporate condom negotiation skills to build confidence among females to effectively negotiate with male partners who have negative views on condom use. Condom negotiation can be accomplished through direct, indirect, verbal, and non-verbal strategies (French & Holland, 2013). Negotiation can include withholding sex or directly requesting a partner to use a condom, both of which have proven effective in increasing condom use. Communication is a key part of condom negotiation (French & Holland, 2013).

Parents can also teach effective communication to promote condom negotiation skills. As stated above, when parents discuss sex openly, adolescents are more likely to delay sexual initiation, have less sexual partners, and practice safer sex (O'Sullivan et al., 2001). Some research shows that sexual education programs that increase parental involvement may have a more positive impact than programs that do not increase parental involvement (Kirby, 2007). States that require sexual education need to work to incorporate communication-building skills into the curriculum. Even though some states promote abstinence-only programs, schools can still take the opportunity to develop communication skills. Even if the skill building is not explicitly directed at condom negotiation, building communication may help to increase the confidence needed for female adolescents and young adults to take control of their sexual experiences.

Conclusion

The United States reports high rates of STDs and pregnancy among female adolescents and young adults. While there are a variety of safer sex methods available to female adolescents

and young adults, no one method provides full protection against both STDs and pregnancy. To ensure complete protection, dual use methods are now being encouraged for this population. This review found that dual use rates remain quite low among female adolescents and young adults. This review also explored the various factors affecting a female's choice of protection. This information can be helpful in successfully targeting the intended population with the goal of increasing dual use rates among female adolescents and young adults in the United States.

Abstract:

Fourteen years ago the Institute of Medicine published *To Err Is Human* which brought to light a problem that was hidden from ~~masked to~~ the public. It stated that 44,000 to 98,000 people died from preventable medical errors annually in the United States. Surgery was found to be the cause of 48 percent of these errors. Thus, surgical safety is a serious public health concern that needs to be addressed. It is important for ~~pertinent to~~ researchers and the public to better understand the data surrounding surgical safety, what interventions have been attempted to alleviate the problem of surgical errors and adverse events, and what action can be taken to make surgery safer in ~~for~~ the future.

Introduction:

The extent to which medical errors occurred wasere unknown to both the public and medical practitioners until 1999 when the Institute of Medicine (IOM) published its landmark report titled *"To Err Is Human".* The groundbreaking report galvanized the public, threw the media into a frenzy, disturbed practitioners, led to congressional hearings and formed millions of angry patients (Wachter, 2004). Understandably, much of the concern revolved around the 44,000 – 98,000 people who die from medical errors annually in the United States, comparable to a jumbo jet crashing every other day. The debate of whether their calculations are correct or exaggerated rages on (Leape, 2000; McDonald et al, 2000). Nevertheless, given their size, it should not matter whether the numbers are exaggerated or not; and the fact that a once ignored danger must now be acknowledged, researched and repaired.

Only hospitals superseded the rush of practitioners trying to understand and change the harsh reality of the report. Hospitals began scrambling to reduce their rates of adverse events. An adverse event is defined as "an unexpected occurrence involving either death, physical, physiological trauma or risk of that occurrence" (Joint Commission, 2013). The reason for this scramble was two-fold. Patient safety is obviously the major concern for all hospitals. Additionally, the monetary aspect plays an important role. Malpractice insurance and settlements totaled in the billions due to adverse events across the nation (Makary, 2012).

Expectedly, national and international organizations stepped into the mix as well. World Health Organization (WHO), National Institute of Health (NIH), Joint Commission, Agency for Healthcare Quality and Research (AHRQ) and the Institute of Medicine (IOM), as well as many others, began researching what can be done to not only reduce the risk of surgical errors but also make surgery safer

overall. Changes began straightaway. Operating room protocols have been amended, checklists have been implemented, and programs such as SCIP (surgical care improvement project) are nearing 100% compliance in nearly all United States hospitals (HHS, 2011). Despite all this, every patient safety organization will say that we are not any closer to surgical patient safety than we should be based on the known findings. Fortunately, the amount of progress made is undeniable (Wachter, 2004). In a survey by Wachter (2004), four hundred physicians were asked whether they believe patient safety was better: forty-five percent thought it had improved; thirty-eight felt it was the same and seventeen felt it was worse. The future looked even more hopeful with nearly seventy percent saying it will be better in five years compared to eleven that thought it would be worse (Wachter, 2004).

Modern surgery as we know it today is just a bit over two centuries old (Bishop, 1995). It is a miracle that a field, which is so dangerous and so embryonic, has evolved from the simplest techniques being deadly to successfully saving someone's life with a heart transplant in such a short period of time. Currently, surgery is a constantly evolving field. New research regarding the most effective, least intrusive and safest techniques is being published constantly. It was just one hundred seventy years ago that Sir John Erikson stated: "The abdomen, the chest and the brain will forever be shut from the intrusion of the wise and humane surgeon." However, today surgeons perform approximately 80,000 procedures of that nature daily (Riskin, 2006).

Thankfully, surgery is an ever-evolving field. Although progress has been made in medicine, practitioners and providers still have a long way to go. Debates continue about why the alarming rates of errors, infections, and adverse events continue. Even though a plethora of interventions have been attempted to mitigate the risk of adverse events, many experts argue that we are no closer to surgery

being safer than we were before the IOM report. This comprehensive literature review will discuss surgical adverse events, what interventional attempts have been made to mitigate those adverse events, and whether or not they have worked. Limitations of this paper are to be mentioned. Literature outside of the United States has only been included on a comparison basis. Thus, this paper focuses on surgical safety in the United States. Additionally, only studies in English have been included in this paper, which might pose data limitations on international research based in the United States. Finally, literature prior to 1991 has been excluded, although data used in some literature goes back to 1984, which might reduce applicability of this paper.

Literature Review:

Although the field of surgery is thousands of years old, modern surgery is less than two centuries old. Pioneer surgeons had three limiting factors that inhibited surgery from progressing into science: hemostasis, pain and infection (Gawande, 2012). Hemostasis, a risk of bleeding was a considerable threat when performing any invasive procedure. It was not until ligatures were invented ~~,~~ that this risk was minimized. However, when introducing a foreign object into the body a risk of infection remained a threat, and thus, ligatures only solved part of the problem. It was not until the mid-19th century that the technique of antisepsis received recognition. Throughout all this, pain to the patient remained a formidable threat~~d~~ until the administration of anesthesia became the norm when performing invasive procedures.

With the three limiting factors of surgery under partial control, modern surgery began ~~its inception~~. Surgery is a field with a history of many ups and downs. Some of that history includes innovative and successful techniques performed in the mid-19th century such as abdominal cyst drainage. However, the low points existed as well such as an amputation surgery with a three hundred percent mortality rate, in which the patient and assistant died of gangrene due to an error by the surgeon and a spectator died of shock (Gordon, 2001).

Surgical errors have been around since surgery was first performed. Doctor Robert Liston, a professor of surgery at University College Hospital in London, was the first surgeon to perform a procedure under anesthesia in Europe. Dr. Liston was a world-renowned practitioner who was able to

amputate a leg in less than two and a half minutes. However, with all the skills he possessed, his three most erroneous surgeries are the ones that forever made him famous. Mistaking an aneurysm for an abscess Dr. Liston slashed open the carotid artery of a young boy. His second most famous case involved the amputation of a leg in less than three minutes; however, due to his enthusiasm he removed the patient's testicles as well. Finally, Dr. Liston was the surgeon who performed the only surgery with a 300 percent mortality rate. During a leg amputation, the lightning quick surgeon amputated several fingers of a young surgical assistant as well. Both the patient and assistant later died of gangrene. Finally he slashed through the coat of a spectator who was terrified that the knife pierced his vitals and he died from fright (Gordon, 1995). Although Dr. Listen's cases are extreme examples, a plethora of errors still happen in the operating room every day.

It is understandable that a field that is so incredibly invasive is extremely dangerous. However, a large discrepancy must be made between medical risk and medical error (Clarke et al, 2007). Medical risk is defined as: the risk of an adverse outcome occurring when performing a procedure. Conversely, medical error is defined as: a preventable adverse event regardless of whether or not it is harmful to the patient (Hofer et al, 2000). Every surgery performed carries with it significant medical risk but surgeries should not carry a possibility of medical error in addition to that risk, or at the least work to mitigate the risk of an error occurring.

After the publication of "*To Err is Human,"* nearly every health organization became a strong advocate of increasing safety in the operating room (and health care in general). A major push occurred in 2008 from the World Health Organization (WHO). Data from fifty-six countries in 2004 showed that the annual volume of surgeries ranged somewhere from 187-281 million.

Although exact numbers of surgical errors are difficult to estimate, based on reporting from industrialized nations, the WHO derived that surgical errors occurred in 3 to 22 percent of inpatient surgical procedures, leading to a death rate of 0.4 to 0.8 percent. The large range in data is indicative of its probable imprecision and of great variances between countries. A skew exists because studies in developing countries indicate a mortality rate of 5-10 percent with major surgery. Nearly half of these adverse events were deemed to be preventable (WHO, 2008). Although the data presented was extrapolated, nonetheless it is clear that based on the evidence, avoidable surgical mortality is a significant public health concern. Although this paper focuses on surgical safety in the United States, it is important to understand international comparisons. Internationally surgical errors have been estimated at approximately seven million, leading to approximately one million preventable deaths according to the WHO. Unfortunately, the United States fares no better than the rest of the industrialized world in adverse event occurrences in the perioperative setting.

Prior to examining adverse events in surgery in the United States, it is important to discuss what exactly surgical errors are, how they differ from adverse events, where they occur, and how they are reported. According to the Joint Commission, a surgical error is an "error or mistake that is committed by health professionals that results in additional harm to the patient". Within this definition there are several subcategories**.** Most common surgical errors result from a wrong-site, wrong-procedure, wrong-patient procedure, occurring approximately in 1 out of every 50,000 to 100,000 procedures or equivalent to 1,500 to 2,000 times per year in the United States. When broken down by data from 2005 the WHO found that in the 126 cases reviewed, wrong-site surgery occurred in 76

percent of cases, 13% occurred on the wrong-patient and 11% occurred as a wrong procedure (WHO, 2008). Another type of error is referred to a retained foreign body, occurring in approximately 1 out of 5,000 to 1 out of 19,000 procedures. However, the likelihood has been estimated to be around 1 out of 1,000 procedures (WHO, 2008).

Conversely, according to the Joint Commission, "an adverse event is an unexpected occurrence involving death or serious physical or psychological injury, or the risk thereof". Serious injury specifically includes loss of limb or function. The phrase "or the risk thereof" includes any process variation for which a recurrence would carry a significant chance of a serious adverse outcome" (Joint Commission, 2011). It is important to note that the terms surgical error and adverse event are not synonymous. Not all surgical errors result in adverse events and not all adverse events transpire due to errors. For example, although a wrong-site aneurysm resection would be considered a surgical error it would not be considered an adverse event, since no death or physical injury occurred to the patient. This distinction is important since this paper focuses on surgical errors; thus, even neutral errors that cause no harm to the patient will be examined. As discussed above, surgical errors resulting in death or serious injury are considered adverse events and will be addressed as such.

Surgical errors can occur in any of the stages of the perioperative setting; preoperative, intraoperative, and the postoperative settings can all be hosts to surgical errors. Identified surgical errors have also been categorized into five types. The first type of error is known as a judgment error. These errors are caused by inadequate knowledge or failure to properly use knowledge, this includes a failure to obtain a consult or to order proper test and are the cause of approximately twenty percent of surgical errors. The most obvious way to minimize the occurrence of this type of error is proper

education of the surgical staff. The second type is a technical error; these do occur and are acknowledged as being part of the residency training process. However, defective or inappropriate equipment can result in a technical error as well. Technical errors comprise approximately ten percent of adverse events in surgery. The third type of errors is an expectations errors caused by an unskilled clinician such as a resident. It is unknown what percent of cases suffer due to this error since it is often ignored. Surgical residency programs often do not have established guidelines or milestones that are to be achieved. Thus, it is common for residents to perform tasks that they are not competent enough to do. The fourth is a systems error, which is not caused by an individual but rather by the entire process and is the cause of nearly sixty percent of all errors. The only intervention to combat this error would be an introduction of scrupulous protocols at every step of the medical and surgical process. Additionally, since no person is at fault during this type of error the traditional system of discipline is not useful to combat it. The final type of error is a mechanical error; it occurs most infrequently and is caused by mechanical equipment failure such an unsharpened scalpel (Krizek, 2000).

Currently, reporting of most adverse events – and by association most surgical errors - remains voluntary for medical providers. Thus, hospitals, outpatient clinics, and other establishments where these events occur can elect not to report an event if it does not meet the criteria described by the National Quality Forum (NQF) (Kizer and Stegun, 2005; Classen et al., 2011). The NQF is a nonprofit, public benefit corporation that was established in 1999 and became operational in 2000. The main purpose of the NQF was to improve United States health care with national standards and public reporting of health care performance data (Kizer and Stegun, 2005). Keeping to that goal, the NQF identified a list of 27 reportable adverse events. This list was not designed to be exhaustive and capture all errors. Rather, it includes errors that are 1) identifiable and measureable, 2) their nature is

influenced by the policies of the facility and 3) they are of concern to both providers and the public. To qualify for this list an event had to be unambiguous, preventable, serious and one or more of the following: 1) adverse, 2) indicative of a problem in the facility's safety systems and/or 3) important for public credibility (Kizer and Stegun, 2005). Examples of some of the 27 events are: wrong site surgery, wrong patient surgery, wrong procedure, retained foreign object, and immediate intra or post-operative death of a healthy individual. Since there is no national reporting system in the United States, only some States require reporting at least some of the types of adverse events as described by the NQF. Additional ways of adverse event exposure can result from communication of a patient, family member, an employee of the organization, or through research and the media. Is it due to this that some researchers believe that the rates of errors are grossly underestimated.

Published studies on medical errors and surgical complications depend mostly on comparable retrospective analyses or self-reporting such as incident reports. According to Krizek (2000), these are the methods of data collection that should be amended. Some problems can be caught before they occur if prospective methods were used. If constant non-punitive prospective surgical patient data is collected, errors can be caught before they occur, akin to automobile makers recalling defective vehicles before they are sent out into the market. For example, if patient records are consistently reviewed for errors while not blaming any particular clinician for possible errors Retrospective error reporting, many believe, understates the incidence of adverse events that is reported in the literature (Mulloy & Hughes, 2007). An additional reason for questionable data is due to medical record review. Traditionally, adverse event data has been collected by medical review; due to the fact that there is also a reluctance to document errors in official medical records for fear of litigation many adverse events could have never been

documented, and thus, never assessed (Krizek, 2000). The difficulty of prospective data collection has led to most analyses of current surgical error data being retrospective medical chart review and possibly flawed. Although some researchers admit the potentiality of retrospective studies being flawed, they provide us with an approximate view of the incidence of surgical error occurrences.

A highly regarded, accepted, and quoted retrospective study of New York State hospitals was done in 1991 by Harvard Medical School utilizing 30,195 medical records. The authors used fairly stringent criteria to determine the risk of adverse events that occurred during hospital stays of surgical patients. The researchers found that adverse events occurred in ten percent of patients; of these 3.7 (1133) percent were deemed critical, using their criteria. The study found that operative events accounted for 48 percent of all adverse events. Negligence was the cause of 27.6 percent of these errors. Out of this, 70.5 percent led to disabilities lasting less than six months, 2.6 percent gave rise to a permanent disability, and 13.6 percent led to death (Brennan et al, 1991). Regrettably, the study was not able to delve in deeper details and further events of surgical adverse events have been missing.

One year later, Dr. Atul Gawande used data from 1992 to follow up with a more in-depth look at surgical adverse events in Colorado and Utah. A review of nearly 15,000 randomly selected non-psychiatric discharged patients ensued; four hundred and two adverse events were identified, with an adverse event rate of three percent. Although the study found that the rate surgical adverse event occurrences were no more likely to occur than non-surgical adverse events, 66 percent of the adverse events were attributed to surgery since more patients received surgeries than other types of intervention. The incidence of such events found by Gawande et al. was three percent, slightly lower than the 3.7 percent found by Brennam et al. (1999). Of the three percent, fifty-four percent were

determined to be preventable. It was also found that 5.6 percent of surgical errors led to death. When extrapolated from the data reviewed for all surgeries in Utah and Colorado, it was determined to have led to 755 preventable deaths in the two states.

Although the variation that leads to the slight change in incidence rate in subsequent studies is unknown, the possibility of a downward trend from previous studies on error incidence rates cannot be disregarded either. The drop in identified errors from 1972, 1984, and 1992 was 4.6, 3.7, and 3 percent, respectively, suggested a downward trend (Gawande et al., 1999). Consistent with previous findings, more than half of adverse surgical events were preventable and nearly fifteen percent led to permanent injury or death (Gawande et al, 1999). The study found that most of the errors that were reviewed were intraoperative and occurred during the procedure, as opposed to postoperatively. Thus, it is clear that the preoperative setting needs improvement. Better coordination of care, as well as a preoperative evaluation of the patient, and an understanding of the procedure being performed can all reduce the possibility of an error occurring (WHO, 2008). Of course, due to the study above being retrospective, the reliability and validity of physicians' judgment and recall should be scrutinized.

Additionally, retrospective studies raise problems of the reviewer's assessment of the physicians' judgment. Some researchers believe that these numbers are underestimated, since medical practitioners are reluctant to document anything that can be interpreted as negligence (Krizek, 2000). It is due to this that retrospective studies discussing medical errors have come under scrutiny and have even been deemed inadequate due to lack of documentation. Data collected after the fact is doomed for the aforementioned reasons (Bosma, Veen & Roukema, 2011; Krizek, 2000). It is thus not all encompassing to attempt to discuss surgical safety while omitting prospective data studies.

In a prospective study done by Krizek in 2000, a total of 1047 patients were used who were admitted to three surgical units in Tampa Bay, Florida. Errors occurred in 480 patients, a remarkable 45.8% of the cohort. In this, 2183 errors or adverse events were identified, of which 462 (21.2 percent) were deemed critical (life-threatening or limb threatening). One hundred seventy-five of the patients in the cohort had at least one serious adverse event. Errors were categorized into nine areas; management complications and surgical errors comprised a large portion of the adverse events identified, 38.1 percent and 19.7, respectively. The study found that not only do adverse events harm the patients, but also providers. Average length of stay for a patient with no adverse event was 8.8 days, compared to those who did experience adverse events who had an average length of stay of 23.8 days, while those with serious adverse events had a 32 day long average length of stay. Nationally, the average length of stay postoperatively is 4.6 days, which costs about 2,000 dollars (AHRQ, 2011). Based on this data, it is clear that adverse events led to a significant increase in not only average length of stay, but costs accrued by the hospital system studied.

However, the limitations of this study should not go unmentioned. Compared to an average length of stay of 4.6 days nationally, the 8.8 day stay presented in this study showed that either the sickest patients from surgical units were chosen or that the hospital selected admitted the sickest types of patients. However, this should have no effect on the incidence of errors. The reporting of this prospective study showed substantially higher rates of errors reported by other retrospective studies, 45.8 percent and 10 percent, respectively.

Additional prospective studies have obtained results that were similar to what Krizek (2000) achieved. Bosma, Veen and Roukema (2011) analyzed the incidence of surgical errors. As with the

study conducted by Krizek, a prospective design was used and provided an opportunity for quality improvement in patient care. They aimed to analyze the incidence, nature, severity and consequences of medical errors.

Bosma, Veen and Roukema defined an error as "a condition or event, unfavorable to the patient's health, causing irreversible damage or requiring a change in therapeutic policy." Furthermore, they classified the severity of complications on a validated four point grading system. The most severe complication resulted in death, then lasting disability, then need for pharmacological or additional medical treatment, and finally minimal harm incurred, grades IV, III, II, and I, respectively.

During the study period of two and a half years, 12,121 patients were admitted to surgical units, with 66 percent being elective and 34 percent being acute. A total of 15,058 surgical procedures were performed on 8384 patients (some patients had multiple procedures). One thousand six hundred thirty-nine patients (19.5 percent) had one or more adverse event occurrence, whereas, 394 of the 3737 patients who were not operated on had adverse events (10.5 percent). Incidence of error was highest in thoracic, vascular and trauma surgery, 9.9, 9.2, and 8.7 percent, respectively. Of all the errors, 94.7 percent had no lasting effect on the patient, although additional intervention, follow-up procedures, and average length of stay all suffered significant increases. These resulted in an increased average length of stay for the patient and of cost to the provider (Bosma, Veen, & Roukema, 2011).

Bosma, Veen, & Roukema showed that errors in surgery are a common problem and – according to their study – accounted for six percent of all admissions. Although most events occurred without long-term harm to the patient, one of every twenty patients had significant consequences resulting in their death or permanent injury. Although prospective data reporting might be of great

importance to patient safety, it is rarely undertaken (2011).

Limitations exist in all studies and the two mentioned above are no different. The biggest problem when analyzing surgical errors is the potentiality of underreporting and missing incidents of surgical errors. Consequently, the figures presented in both studies may be grossly underestimated. Underreporting is especially true when residents are the ones to register complications, which occurred in both studies (Bosma, Veen & Roukema, 2011; Krizek, 2000). Additionally, the Hawthorne effect can tend to improve outcomes since the surgeons knew they were being evaluated. Finally, when compared to retrospective data of the same nature, prospective data studies presented a much smaller sample size. However, Bosma, Veen & Roukema (2011) and Krizek (2000) laud the prospective data collection, which can provide an outstanding opportunity for prevention and quality improvement by actively reviewing charts and records, which can potentially reduce the incidence of errors with any identified consequences to the patient.

Patient safety is not all that is at risk with surgical errors. Although providers should always have patient safety goals in mind, monetary incentives should not go unmentioned. The attributed cost of the 44,000 – 98,000 people that die from medical errors each year is $17 – $29 billion. These costs are mostly attributed to increases in average length of stay, follow-up visits and surgeries and lawsuits. Of this, according to a study funded by the AHRQ, surgical adverse events accrued an annual cost of nearly 1.5 billion dollars when generalized to the nation. Costs of errors continue to accrue even after the patient has been discharged (Encinosa & Hellinger, 2008); these numbers can again be underestimated due to underreporting of the adverse events that occur.

Surgical errors are also connected with social cost prompted by the damage produced.

Goodman et al., reports that the value of lives lost and disabilities prompted by surgical errors in 2006 ranged from 393 to 958 billion dollars, which is equivalent to 18-45 percent of the total United States health care spending (2011). Thus, lowering costs of errors can potentially reduce United States health care costs. Additionally, the study attests that the chance of a patient dying from a cause other than the one he or she was hospitalized for is one in two hundred and that adverse events occur in every one of twenty admissions that lead to surgery (Goodman et al., 2011).

Now we have established that adverse events in the perioperative setting are a serious public health concern. These errors not only cause adverse events in patients, but are also related to health care cost and increased length of stay. Although billions of health care dollars have been invested in improving quality, surgery continues to include not only risk but also possibility of an adverse event occurring. It is important to understand the impediments and challenges that have prevented the rates of surgical errors dropping since the IOM published "*To Err Is Human*".

The World Health Organization (2008) and Krizek (2000) identified six clinical barriers in surgery that might have inhibited improvement in quality as was expected: Inadequate data about incidence of adverse events, inadequate practice guidelines, a culture of blame, difficulty in truth telling, a need to compensate injured patients, and the complexity of the surgical setting.

Inadequate data reporting has led physicians to believe that the problem is not as prevalent as portrayed. Due to data extrapolations - as with To Err is Human where data from two states were extrapolated nationwide-, inaccurate audits and medical records occasionally being incomplete, physicians often disregard data on surgical errors. Additionally, a provider will on average only be responsible for one preventable death every twelve years – hardly a cause for alarm in a field where

death is common. Thus, physicians will often be unaware of the potential harm they have caused in the grand scene of their practice (Mechanic et al., 2005).

A surgeon's training and the hospital's culture can often cause inadequate practice guidelines. Oftentimes a providers training in residency will not be updated frequently enough to keep up with evidence-based practice, and even more shockingly, occasionally hospitals will take too long to disseminate and upgrade order sets to reflect the newest best practices. It is inexcusable to disregard evidence-based medicine. A provider's job is to remain up to date on current practice guidelines. A surgeon not adhering to current accepted practice guidelines is doomed to cause adverse events (Krizek, 2000).

The field of medicine is famous for its culture of finger pointing. For example, if an error occurs intraoperatively the surgeon will blame anesthesiologist who will blame the medical doctor will who blame the surgeon. It is due to this culture that providers will sometimes hide minor adverse events to protect themselves from blame. This often leads to worse outcomes for the patient and costly investigations. Although many hospitals are encouraging a non-punitive environment for reporting errors, most clinicians will still opt out (Mechanic et al., 2005). This culture of blame is directly related to the two other barriers, truth telling and compensation to an injured patient. Surgeons will sometimes not disclose errors to patients and their families if they are not life threatening for fear of litigation (Mavroudis 2005; Krizek, 2000).

The sixth barrier in improving surgical safety is its complexity. Even the most seemingly simple and straightforward procedures require dozens of steps and checklists. Each of these steps allows an opportunity for failure and the possibility of an error occurring. From identifying the correct site on the

correct patient to sterilizing surgical equipment, each step is infinitely important and must be completed flawlessly to prevent an adverse event from occurring (Gawande, 2012). Ultimately, a surgical team that works effectively will produce the best outcomes. Unfortunately, surgical teams often have little understanding of how to better promote efficient collaboration, a skill that reflects on improved patient outcomes (WHO, 2008).

In additional to the clinical barriers, progress in reducing surgical errors has been slow for political reasons. Given the enormity of the problem – thousands of preventable deaths and millions of preventable injuries – and the evidence-based knowledge of how to lessen them, it is anticipated that this would have to be a large national effort. Due to the fact that the United States lacks a health care governing organization, the campaign is being spearheaded by organizations such as The Joint Commission. Unfortunately, AHRQ funding is often scarce and action plans seldom get fully carried out (Leape, 2000). Furthermore, the edginess that was association with the publishing of *"To Err Is Human"* has subsided. In fact, when the public was polled just three years after the report was published, sixty percent thought that the number of preventable deaths was less than five thousand (Mechanic et al., 2005). Loss of public demand, lack of funding and little public support for expanding governmental regulations have all contributed to the decelerated progress of surgical patient safety.

An often overlooked barrier when trying to bring about policy change is monetary insufficiency. Due to the fact that no governmental health care organization exists in the United States, funds are lacking in our health care system. Without governmental funding, hospitals and practitioners are unlikely to adopt any system or policy that leads to a net cost. Regrettably, federal funding does not guarantee results either (Mechanic et al., 2005).

Shojania and Thomas offer two opinions on why progress in the surgical safety arena has been so slow. First, investments into patient safety pale in comparison to the billions invested in biomedical research. The National Institutes of Health (NIH) has an annual budget of nearly 30 billion dollars, roughly sixty times that of the AHRQ (AHRQ, 2013). The "war on cancer" announced in 1971 by Richard Nixon has consumed hundreds of billions of dollars. The United States National Cancer Institute alone spent 105 billion dollars. while other funding and philanthropic agencies have spent countless billions more. While the United States can boast of some amazing outcomes, over all the mortality rate of cancer has only dropped five percent since 1950 (Shojania & Thomas, 2013). This miniscule impact has occurred over a significantly longer time period than the patient safety initiatives have even existed. Additionally, cancer and biomedical research had a significant clinical head start as well. Existing clinical and biological research was used as a springboard to launch new research and clinical trials, something that is sorely lacking in patient safety research (Shojania and Thomas, 2013).

Secondly, for progress in patient safety to occur, Shojania andThomas believe that three achievements need to occur: Identification of interventions that reduce common adverse events, effective dissemination of effective interventions, and development of a tool to measure improvements in patient safety problems. Sadly, none have transpired. Very few effective and evidence based interventions exist and those that exist have not been widely adopted. Additionally, they believe that even if we were to make progress in surgical safety, the current "gold standard" instrument for measuring progress – as used in the Harvard Medical Practice Study of New York Hospitals and Atul Gawande's study of hospitals in Utah and Colorado (Brennam et al, 1991; Gawande et al., 1999) – are too blunt to measure slow progress over time.
